Group G Streptococcal Bacteremia in Jerusalem

Ronit Cohen-Poradosu,* Joseph Jaffe,* David Lavi,* Sigal Grisariu-Greenzaid,* Ran Nir-Paz,* Lea Valinsky,† Mary Dan-Goor,‡ Colin Block,* Bernard Beall,§ and Allon E. Moses*

Group G Streptococcus (GGS) can cause severe infections, including bacteremia. These organisms often express a surface protein homologous to the Streptococcus pyogenes M protein. We retrospectively studied the characteristics of patients from the Hadassah Medical Center with GGS bacteremia from 1989 to 2000. Ninety-four cases of GGS bacteremia were identified in 84 patients. The median age was 62 years, 54% were males, and 92% had underlying diseases (35% had a malignancy, and 35% had diabetes mellitus). The most frequent source for bacteremia was cellulitis (61%).

emm typing of 56 available isolates disclosed 13 different types, including 2 novel types. Six patients had recurrent bacteremia with two to four bacteremic episodes, five had chronic lymphatic disorders, and two had emm type stG840.0 in every episode. Recurrent bacteremia has not been described for invasive group A Streptococcus. We describe an entity of recurrent GGS bacteremia, which is associated with lymphatic disorders and possibly with emm stG840.0.

Large colony-forming group G β-hemolytic streptococci (GGS) were first isolated in patients with puerperal sepsis in 1935 (1). GGS are known to be commensals and pathogens in domestic animals. In humans, they may colonize the pharynx, skin, gastrointestinal and female genital tract (2). In recent years, GGS have been reported with increasing frequency as the cause of a variety of human infections, such as pharyngitis, cellulitis, meningitis, endocarditis, and sepsis (2–8). Bacteremia attributable to GGS have been related to underlying conditions, such as alcoholism, diabetes mellitus, malignancy, intravenous substance abuse, or breakdown of the skin (2–7,9,10).

The taxonomy of these organisms has been reevaluated in recent years. The Lancefield group G carbohydrate may be encountered in several β-hemolytic streptococcal species, including Streptococcus anginosus and S. canis, but mainly in S. dysgalactiae subsp. equisimilis, which is the subject of our study (11). This subspecies also hosts variants with Lancefield group A, C, and L carbohydrates. The subspecies epithet was determined by gene sequencing of the group C species previously named Streptococcus equisimilis, which showed it to be indistinguishable from group G S. dysgalactiae. This finding resulted in the description of a new taxon, S. dysgalactiae subsp. equisimilis. The true proportions of the non-G carbohydrates among members of this taxon are difficult to estimate. In a prospective, population-based study of invasive S. pyogenes infections (12), we found six isolates with the group A antigen to be S. dysgalactiae subsp. equisimilis. Among isolates from infections attributable to S. dysgalactiae subsp. equisimilis, the group C and G antigen was found much more commonly in human infections than group A (GAS) (11).

S. dysgalactiae subsp. equisimilis and S. pyogenes share virulence factors such as streptokinase, C5a peptidase, M protein, streptolysin S, and certain exotoxin genes (13–18). The M protein is an important virulence factor because it confers resistance to phagocytosis (19). M proteins of GAS and GGS obtained from human infections have similar biologic, immunochemical, and structural features (20). The substantial polymorphism exhibited by GAS M proteins has also been described for GGS (21). We have conducted a 12-year retrospective study to establish the incidence, clinical features, epidemiologic characteristics, and emm typing of GGS isolates that cause bacteremia in a large tertiary-care center in Jerusalem, Israel.

Materials and Methods

A retrospective study was conducted from 1989 through 2000 at the Hadassah Hospitals, Jerusalem, Israel. This is a 1,000-bed, tertiary-care center with all major disciplines represented, including hematology, oncology, and...
bone marrow transplantation. The mean number of annual admissions during the study period was 62,433.

Clinical Characteristics

We reviewed the records of all patients in whom a positive blood culture of GGS was reported. Demographic and clinical data were collected. Death rates were measured only during hospitalization. Descriptive statistics were performed with the SPSS (SPSS Inc., Chicago, IL) statistical package release 11.01. The Fisher exact test was used for differences in proportions. A two-sided p value of <0.05 was considered significant.

Microbiologic Methods

Patients with GGS bacteremia were retrieved from the microbiology laboratory database of bacteremia. No more than one isolate per admission was included. Clinical specimens were collected and handled according to standard protocols. During the study period, the BACTEC 460 radiometric system and the BacTAlert (Organon Teknika, Belgium) blood culture system were used.

All catalase-negative, chain-forming, gram-positive cocci that were β-hemolytic on 5% sheep blood agar were Lancefield serogrouped by using kits according to the manufacturer’s instructions (PathDox Strep Grouping, DPC Diagnostic Products Corporation, Los Angeles, CA). We had 56 isolates available for further analysis. These had been stored at –70°C in the laboratory collection of blood culture isolates. All isolates displayed large colonies and did not belong to the S. anginosus group (“S. milleri”).

Molecular Methods

An overnight growth was resuspended in saline and heated at 70°C for 15 min. Bacteria were then resuspended in 50 µL of 10 mmol/L Tris, 1 mmol/L EDTA, pH 8. Ten microliters of mutanolysin (3,000 U/mL) and 2 µL hyaluronidase (30 mg/mL) were added. After incubation at 37°C for 30 min and heat inactivation at 100°C for 10 min, the supernatant was subjected to polymerase chain reaction (PCR). Fifty-six GGS isolates were emm typed. PCR was performed as described (http://www.cdc.gov/ncidod/biotech/strep/strepblast.htm), where emm type was determined (22).

The 12 strains from recurrent infection were analyzed by pulsed-field electrophoresis (PFGE). Chromosomal DNA was digested with Smal and prepared and analyzed as described with minor modifications (23).

Results

The 504 bloodstream isolates of β-hemolytic Streptococcus from 1989 through 2000 included the following: 232 (46%) group A, 171 (34%) group B (GBS), 94 (19%) group G, and 7 (1.4%) groups F and C. The 94 episodes of GGS bacteremia involved 84 patients, 6 of whom had recurrent infections. Patient characteristics are summarized in Tables 1 and 2. The annual incidence of GGS bacteremia was 0.0–0.2 cases/1,000 admissions during the 12-year study; the incidence ranges for GAS and GBS were 0.2–0.48 and 0.19–0.3, respectively (Figure 1).

Five patients died, but only two of the deaths were directly attributed to the GGS bacteremia. The other three deaths were related to malignancy in two patients and congestive heart failure in one.

Of the 56 GGS isolates available for emm typing, we found 13 emm types (including 2 subtypes of stG6: stG6.0 and stG6.1). These types included stG507.1, a variant of emmLG507.0 (GenBank accession no. X79527) and stG6792.0 (identical to a partial gene sequence, accession no. X79527).

†Soft tissue infection, pressure sore attributable to diabetes.
no. AF495842, listed from a blood isolate of S. dysgalactiae subsp. equisimilis, which were not in the database. The patient with the stG507.1 bacteremia had cellulitis, and two patients had the stG6792.0 strain: one was a 17-year-old patient with venous malformations of the leg and pelvis who had GGS sepsis and multiorgan failure, and the other was a 92-year-old man with diabetes and cellulitis. No association was found between emm type and year of study, season, source of infection, or cellulitis location.

Six patients had recurrent bacteremia, ranging from 2 to 4 episodes per patient (Table 3). All six patients had a community-acquired recurrent cellulitis and were given treatment similar to that received by patients who did not have a recurrent infection. Five patients had chronic lymphatic abnormalities at the infection site compared to 11 of 42 patients with nonrecurrent cellulitis (odds ratio [OR] 14.1, 95% confidence interval [CI] 1.5–134.3, p = 0.012). Two patients had recurrent infection with the same emm type, stG840.0 (one patient had three episodes, 1 and 7 months apart; the other patient had 2 episodes, 6 months apart). Three patients had a different emm type each episode. The isolates of the patient with four recurrent episodes were not available for emm typing. PFGE results indicated that isolates recovered from the same patient that shared the same emm type were highly genetically related (Figure 2).

Discussion

GGS are widely distributed in nature and are recognized as both commensals and pathogens in animals as well as in humans. S. dysgalactiae subsp. equisimilis is part of the normal bacterial flora in humans. S. dysgalactiae subsp. equisimilis is the most common species of large colony-forming serogroup G streptococci that is β-hemolytic on sheep blood agar. The animal-associated S. canis has rarely been implicated as a human pathogen, although accurate data are not available (11, 24). Asymptomatic pharyngeal carriage of GGS has been described in up to 23% of humans (25), and vaginal carriage in 5% of asymptomatic puerperal women (1).

This 12-year retrospective survey identified 94 episodes of GGS bacteremia at the Hadassah-Hebrew University Medical Center. It is one of the two largest series of GGS bacteremia described in the literature to date (26). Some similarities were found in the epidemiologic characteristics of group G streptococcal bacteremia between our study and other studies. Patients were predominantly elderly men. Most patients (92%) had underlying diseases, similar to those (74%–92%) reported previously (2–6, 9).

As shown by Auckenthaler et al. (3) and Woo et al. (6), malignancy was one of the most important underlying conditions associated with GGS bacteremia, affecting 35% of our patients. In our patients, the most common malignancy associated with cellulitis was carcinoma of the breast. The most common source of infection among patients with bacteremia with a known source was soft tissue infection, especially cellulitis (61%), 66% of these infections were confined to the lower limbs. Similarly, 48% of our patients with cellulitis had an underlying skin lesion; in 35% of the patients, it was related to lymphatic abnormalities. These abnormalities were mostly attributed to malignancy, surgery, or radiation. Two patients had a congenital lymphatic malformation.

Nineteen percent of our patients had primary bacteremia, which is within the range (11%–52%) described by others (2, 3, 6, 7). The death rate in our study (5%) was lower than that previously reported (8%–30%) (3, 6, 9). One reason for this finding may be the relatively younger age of our patients: Only 22% of our patients were >75 years of age compared to those from Sylvetsky’s group, where 63% were >75 years of age (9). The small number of patients who eventually died of bacteremia precluded analysis of risk factors associated with death.

In contrast to the previous study from a different hospital in Jerusalem, Israel, describing GGS bacteremia during

the same years as our study (9), the yearly incidence of
GGS bacteremia did not increase. The dissimilarity in our
two groups may be attributable to the differences in ages of
the patients and the proportion of men. In addition, the
other hospital is a community hospital with a large geri-
atrie department, without neurosurgery or bone-marrow
and solid organ transplants.

A noteworthy finding in our series was the high fre-
cency of recurrent GGS bacteremia. We identified six
patients with bacteremia, all of whom had recurrent cel-
lulitis. Five had lymphatic drainage abnormalities. Two
patients had recurrent bacteremia attributable to the same
emm type (stG840, patients 1 and 2, Table 3). PFGE results
indicated that within each patient the isolates recovered at
different time points were clonal (Figure 2) but that the
two pairs of stG840 isolates had differing PFGE patterns,
which suggests that they were different clonal types.

Since two of the patients with recurrent bacteremia had
an infection by the same clone, these infections may have
been relapses. Recurrence of bacteremia suggests that the
initial infection may not provide protective immunity. The
question of protective immunity to this bacterium is
addressed by Bisno et al. in a murine model of recurrent
GGS cellulitis (27). Despite recurrent skin challenge with
GGS, the lesion did not decrease in severity, size, or time
to heal. Bisno et al. found that, despite the development of
demonstrable humoral immune response to M protein,
acquired protective immunity did not occur. Possibly GGS
downregulates M protein in vivo, thus allowing it to evade
these specific antibodies. Immediately initiating antibiotic
therapy for the first GGS infection might contribute to the
low level of immunity, as has been demonstrated in cases
of recurrent GAS tonsillitis (28).

Cellulitis can recur in extremities or other sites where
venous and lymphatic circulation has been compromised
by processes such as malignancy, lymph node dissection,
prior irradiation, trauma, or saphenous venectomy
(10,29,30). Nongroup A β-hemolytic streptococci have
been implicated as a major cause of cellulitis in the setting
of circulatory compromise (31,32). Focusing on the 48
patients with cellulitis, we found that recurrent cellulitis
with bacteremia was 14.1 times more likely to develop in
patients with lymphatic drainage abnormalities when com-
pared to patients without such abnormalities. Our report is
the first to describe the phenomenon of recurrent GGS cel-
lulitis associated with bacteremia in patients with lymphat-
ic abnormalities. Recurrent GGS bacteremia seems to be
more common than recurrent GAS bacteremia. In our
study of 90 patients with GAS bacteremia (33) who were
admitted to the Hadassah Medical Center during a 6-year
period, none had a recurrence compared to 6 of 84 patients
in this study (p < 0.013). Our patient with four recurrences
of GGS bacteremia had in effect five additional episodes,
which were not included in our report. Three episodes
were cellulitis with GGS bacteremia at other hospitals, and
two episodes were severe cellulitis without proven bac-
teria. These cases are examples of recurrence of GGS
infection in a manner not known to occur with GAS. A
recent report suggested that allelic variation of human
leukocyte antigen II contributes to the differences in sever-
ity of GAS infections (34). The relationship between bac-
terial factors and host mechanisms of defense in this
patient and others with recurrent bacteremia needs further
investigation.

To illuminate the unique characteristics of patients with
GGS bacteremia, we compared our group of GGS bac-
teremia patients with two groups of GAS bacteremia
patients (33,35). Sex and age of the patients with GGS bac-
teremia were similar to those with GAS bacteremia in a
retrospective study. However, when we compared patients
with GAS bacteremia from our hospital participating in a
nationwide prospective, population-based study, GGS
patients were older and more likely to be men than the
GAS patients (35). Thus, the characteristics of the GGS
patients may reflect institutional and selection bias attrib-
utable to different study methods and may not be a true
tendency for older patients.

Serologic M typing was developed years ago for GAS
typing, but it has also been used for GGS (36). M protein
encoded by emm is a virulence factor of GGS similar to the
GAS surface protein (20). emm typing for both GAS and
GGS is based on the heterogeneity of the 5’ ends of the
gene, which give rise to different sequence types. More
than 120 emm types are recognized for GAS, and approxi-
ately 40 types of GGS and group C Streptococcus (GCS)
have been identified (http://www.cdc.gov/ncidod/
biotech/strep/emmtype.htm). Despite the similarities
between GAS and GGS, Geyer and Schmidt (37) found
that in GCS and GGS, two types of arrangements in the
emm region differ significantly from the known types of
mga region in GAS. The conclusion was that Mgc is relat-
ed to Mga proteins of various types of GAS but forms a
distinct cluster.
nontypeable. Kalia et al. (40) found 13 for GAS (12). The inability to type a large proportion of GGS by the older serologic method is similar to the situation that exists (39). The inability to type a large proportion of GGS by the isolates, 40 (31%) could be serotyped with six antisera (38). Of 128 ing for 103 isolates of GGS. Fifty-six isolates (54%) could be serologically typed into eight serotypes (38). Of 128
[stC previously described for GCS (18,42–45), as well as potential genetic transfer or intrage-

transfer of virulence loci between GAS, GGS, and GCS (Beall, unpub. data). Kalia et al. described a few GCS emm types, which in our study were found in group G streptococci. Certain types are occasionally found in both GGS and GCS (Beall, unpub. data).}

In previous studies, Lawal et al. used serologic M typing for 103 isolates of GGS. Fifty-six isolates (54%) could be serologically typed into eight serotypes (38). Of 128 isolates, 40 (31%) could be serotyped with six antisera (39). The inability to type a large proportion of GGS by the older serologic method is similar to the situation that exists for GAS (12).

In our 56 GGS isolates available for sequence typing, we found 13 emm types. None of our isolates were emm nontypeable. Kalia et al. (40) emm typed 18 GGS isolates from human infections obtained from various countries. They found 13 emm types, the most common of which was stG480.0 (3 of 18 isolates compared to 3 of 56 in our study); our most common type was stG485.0 (10 of 56 isolates).

Thus, emm typing provides a useful tool for identifying isolates when compared to traditional M typing.

Tyrrell found a correlation between clusters of GAS M types and patient age (41). We could not find a correlation between emm type and clinical features such as patient sex, age, and source of infection or cellulitis location, although our database may not be sufficiently large to draw these correlations.

We found among our GGS isolates emm types that were previously described for GCS (stC36.0) and for GAS (stG245.0). Although stG245.0 was originally associated with S. dysgalactiae subsp. equisimilis harboring group A antigen, it is usually associated with GGS (B. Beall, unpub. data). Kalia et al. described a few GCS emm types, which in our study were found in group G streptococci. Certain types are occasionally found in both GGS and GCS (Beall, unpub. data). The dynamics of interspecies transfer of virulence loci between GAS, GGS, and GCS (18,42–45), as well as potential genetic transfer or intragenomic events causing interconversion of group antigen types, remains to be resolved. Our findings that several isolates with emm type stG840 have different PFGE patterns may support the notion that isolates of GGS with the same emm type are not of the same clone. The relationship between GGS emm type and clone remains to be examined. In general, GAS emm typing, when restricted to the same geographic area and time period, is indicative of clonal type; however Beall et al. (46) demonstrated numerous examples of apparently unrelated GAS strains (as judged by independent T agglutination phenotype and opacity factor [sof] sequence) sharing the same emm sequence type, and, more recently, nonrelatedness between distinct GAS strains of identical emm types has been demonstrated through MLST (47).

In summary, we describe 94 cases of GGS bacteremia, observed mainly in older patients with underlying medical conditions. The most frequent portal of entry was the skin.

The high rate of recurrence of GGS bacteremia was an unusual and unexpected finding. Clinicians should be alert to this phenomenon, which seems to be more common than recurrent GAS bacteremia. We found that lymphatic drainage disorders were a highly significant risk factor for recurrence, and that emm type stG840.0 may have a special role in recurring disease.
