We describe 4 cases of *Legionella pneumophila* serogroup 13–associated pneumonia. These cases originate from a broad geographic range that includes Scotland, Australia, and New Zealand. *L. pneumophila* serogroup 13 pneumonia has a clinically diverse spectrum that ranges from relatively mild, community-acquired pneumonia to potentially fatal severe pneumonia with multisystem organ failure. All cases were confirmed by culture and direct fluorescent antibody staining or indirect immunofluorescent antibody tests. Proven or putative sources of *L. pneumophila* serogroup 13 infections in 2 patients included a contaminated whirlpool spa filter and river water. An environmental source was not found in the remaining 2 cases; environmental cultures yielded only other *L. pneumophila* serogroups or nonpneumophila *Legionella* species. We describe the clinical and laboratory features of *L. pneumophila* serogroup 13 infections. *L. pneumophila* serogroup 13 pneumonia is rarely reported, but it may be an underrecognized pathogenic serogroup of *L. pneumophila*.

**The Cases**

**Case 1**

A 27-year-old woman was admitted to an intensive care unit in Glasgow, Scotland, after she had nearly drowned in estuarine water. On admission, her vital signs were as follows: core body temperature 32.8°C, pulse 92 beats per min, blood pressure 90/65 mm Hg, respiratory rate 28 breaths per min, and Glasgow Coma Scale score 13/15. Arterial blood gas analysis on 100% oxygen showed partial arterial oxygen pressure (PaO\(_2\)) 46 mm Hg (reference range [RR] >90 mm Hg), PaCO\(_2\) 48 mm Hg (RR 25–35 mm Hg), and bicarbonate 16.2 mmol/L (RR 24–30 mmol/L). Her blood biochemistry showed hyponatremia and hypokalemia. Chest radiograph showed bilateral consolidation. She was intubated, given ventilatory assistance, and actively rewarmed; inotropes were administered, and empiric intravenous cefotaxime and metronidazole were given. With the patient's further clinical deterioration, intravenous vancomycin replaced metronidazole on day 6. On day 7, high-dose methylprednisolone was administered for worsening respiratory function and chest consolidation. She was intubated, given ventilatory assistance, and actively rewarmed; inotropes were administered, and empiric intravenous cefotaxime and metronidazole were given. With the patient's further clinical deterioration, intravenous vancomycin replaced metronidazole on day 6.
radiographic evidence of acute respiratory distress syndrome. Given the patient’s poor clinical response, on day 14, intravenous clarithromycin and gentamicin were given, with intravenous ciprofloxacin added 24 hours later. Acute renal failure required hemofiltration, and respiratory function deteriorated further on day 15, despite prone ventilation and nitric oxide therapy. On day 18, she died of refractory hypoxemia and multisystem organ failure. A tracheal aspirate collected on day 14 plus postmortem lung tissue samples subsequently yielded colonies of a Legionella species on buffered-charcoal yeast extract (BCYE) agar (Oxoid Ltd., Basingstoke, England). L. pneumophila serogroup 13 infection was diagnosed by mip gene sequencing of the isolate, which demonstrated 99% homology with the type strain of L. pneumophila serogroup 13 (GenBank accession no. AF022327). Seroconversion was demonstrated retrospectively by indirect immunofluorescent antibody (IFA) against monoclonal L. pneumophila serogroup 13 antisera, with a titer rise from <1:32 on admission to 1:512 on day 12. Domestic or nosocomial sources of legionellosis were not sought. Nevertheless, several months later, estuarine water samples were taken near the site of immersion; cultures were negative for Legionella spp.

Case 2

A 51-year-old man who was undergoing induction chemotherapy for acute myeloid leukemia at Royal Perth Hospital, Australia, was initially given regular and extended periods of home leave in the first week after chemotherapy. However, on day 12 neutropenic typhlitis developed, and a right hemicolectomy was performed. This procedure was followed the next day by the onset of dyspnea, nonproductive cough, and persistent fever. Chest radiograph showed left lower lobe consolidation, and meropenem with teicoplanin was administered empirically. He initially remained profoundly neutropenic (neutrophil count ×10⁹/L [RR 2.0–7.5 ×10⁹/L]). Two days later his hypoxemia and chest radiograph results had worsened, and trimethoprim-sulfamethoxazole, amphotericin B, and roxithromycin were administered. On day 18, he had extensive consolidation that involved most of both lung fields, and his neutrophil count had increased to 2.46 ×10⁹/L.

Bronchoscopic samples collected on day 19 were positive for Legionella species antigen by direct immunofluorescent monoclonal antibody stain (DFA) (Genetic Systems, Seattle, WA, USA), but results of his Legionella urinary antigen test (Binax Now, Binax, Portland, ME, USA) were negative. Four days later, Legionella species were isolated on BCYE agar (Oxoid Ltd.) and confirmed by DFA (Legionella Poly-ID Test Kit, Remel, Lenexa, KS, USA) and also by L. pneumophila serogroup 2-14 (LP-2-14) antisera (MarDx Diagnostics, Scotch Plains, NJ, USA). Environmental samples were taken of both hospital and home water. All isolates were then referred to the Australian Legionella Reference Laboratory, Institute of Medical and Veterinary Science, Adelaide, Australia, for typing. Typing confirmed that the clinical isolate was L. pneumophila serogroup 13, both by monoclonal antisera (MarDx Diagnostics) and mip gene sequencing. Hospital water samples yielded L. pneumophila serogroup 10 from both a hand basin cold-water outlet in the patient’s room and a cold-water drinking fountain on an adjacent ward. Restriction fragment length polymorphism (RFLP) and pulsed-field gel electrophoresis (PFGE) typing confirmed that the clinical and environmental isolates were genotypically distinct. The patient was then given intravenous erythromycin followed by oral ciprofloxacin for 3 weeks; subsequently, he made a slow but complete recovery. Testing the patient’s home potable water supply yielded only L. feeleii.

Case 3

A 48-year-old, previously healthy man was admitted to the hospital in Christchurch, New Zealand, with a 6-day history of increasing dyspnea and a 4-day history of watery diarrhea. He also complained of a dry cough, myalgia, loss of appetite, and poor fluid intake. He appeared flushed and unwell and had dry mucous membranes. His vital signs were the following: temperature 39°C, pulse rate 103 beats per min, blood pressure 154/83 mm Hg, respiratory rate 22 breaths per min, and oxygen saturation 94% on room air. His leukocyte count was 6.1 × 10⁹/L (RR 4.0–10 ×10⁹/L), and his serum sodium and potassium levels were 130 mmol/L (RR 136–146 mmol/L) and 3.3 mmol/L (RR 3.5–5.0 mmol/L), respectively. Liver biochemistry was abnormal. His C-reactive protein (CRP) was >220 mg/L (RR <10 mg/L). Chest radiographs showed pneumonia with segmental consolidation of the lingula and left lower lobe.

The patient’s temperature continued to increase to 39.4°C and returned to normal only after 8 days, despite prompt initiation of intravenous amoxicillin and clarithromycin. Liver biochemistry initially deteriorated, peaking on day 6, thereafter slowly returning to normal when the patient was discharged 11 days after admission.

After 6 days of culture on BCYE agar (Oxoid Ltd.), Legionella spp. were isolated from sputum collected on the day after admission. The isolate was typed by Environmental Science and Research Limited (ESR), Communicable Diseases Group Laboratory Services, Porirua, Wellington, New Zealand. A strong positive reaction was seen to polyvalent antisera for L. pneumophila serogroups 1–14 (Monoclonal Technologies Inc., Alpharetta, GA, USA). Monoclonal antisera (Monoclonal
Technologies Inc.) gave a strong positive reaction to *Legionella* strain 82A3105 (CDC 1425-CA-H; ATCC 43736), which identified the isolate as *L. pneumophila* serogroup 13 (David Harte, pers. comm.).

Public health service investigation of the patient’s home yielded *L. pneumophila* serogroup 13 from the filter of an outdoor whirlpool spa. The patient recalled cleaning this filter several days before falling ill. One month later the patient had made a good recovery, although he was easily fatigued.

**Case 4**

A 56-year-old man was admitted to the hospital in Christchurch, New Zealand, with a 1-week illness characterized by myalgia, nausea, sweats, and chills but no respiratory symptoms. He was a nonsmoker with negligible alcohol intake; however, his past history included aortic dissection requiring aortic valve replacement.

On admission he was afebrile, blood pressure was 112/66 mm Hg, and his respiratory rate was 16 breaths per min. His chest was clear to auscultation, but his oxygen saturation was 91% on room air, and chest radiograph showed patchy bibasal consolidation. Leukocyte count and serum sodium level were both normal, but his CRP was elevated to 176 mg/L (RR<10 mg/L). Liver biochemistry was slightly abnormal.

He was treated empirically for possible prosthetic valve endocarditis with intravenous penicillin and gentamicin. On the day after admission, he had productive cough and sharp, left-sided chest pains; a temperature of 39°C ensued. Examination showed left basal dullness with bibasal crackles and left basal bronchial breathing. However, he improved rapidly without specific antimicrobial therapy for legionellosis and was discharged 5 days later.

A sputum sample collected on day 2 yielded *Legionella* species after 9 days of incubation on BYCE agar. With the abovementioned methods, ESR typed the isolate as *L. pneumophila* serogroup 13. Extensive investigations by the local public health services yielded *L. micdadei* from spa whirlpool water where the patient regularly swam.

**Discussion**

The patients we report had typical signs and symptoms of *Legionella* pneumonia, including headache, anorexia, dry cough, and fever, often with hyponatremia and abnormal results of liver function tests (7). Patients had hypoxemia, and disease often involved multiple lobes or both lungs on chest radiograph (7). However, these patients generally had minimal preexisting illnesses, apart from the patient with acute myeloid leukemia who was undergoing chemotherapy. The outcome for 3 of our patients was positive, including the patient with an underlying hematologic malignancy and neutropenia; legionellosis is often associated with a markedly elevated death rate in these cases (3,7,8). The patient who died was severely ill after nearly drowning and had aspiration pneumonitis. Moreover, specific therapy that was effective against legionellosis was not started until 14 days after the putative infection; delay in administering appropriate therapy is known to adversely affect outcome (7,9).

*L. pneumophila* is responsible for >90% of infections caused by members of the family Legionellaceae (1,3,7). *L. pneumophila* serogroups 1, 3, 4, and 6 cause most human infections (1,3,7). An international survey found that of 15 serogroups of *L. pneumophila*, 79% of all culture- or urine antigen–confirmed infections were caused by *L. pneumophila* serogroup 1 (8). Legionellae are fastidious organisms that are not readily recovered from routine diagnostic media; indeed, an American College of Pathologists’ survey indicates that 32% of clinical microbiology laboratories could not grow a pure culture of *L. pneumophila* (10). All of our isolates grew only on specialized media. Failure to diagnose legionellosis in many hospital microbiology laboratories is generally due to a limited availability of specialized media and expertise in the culture of legionellae.

In the United States, from 1980–1998, clinicians have increasingly relied on urinary antigen tests to diagnose legionellosis. Use of these methods has led to an increase in *L. pneumophila* serogroup 1 diagnoses from 0% to 69%, with a corresponding decreased frequency of serogroups other than 1 from 38% to 4% (11). Urinary antigen tests do not reliably diagnose non–serogroup 1 *L. pneumophila* infections (12,13), as illustrated by Benson et al., who found sensitivities of 35% (Binax EIA) and 46% (Biotest-EIA), respectively. However, no isolates of *L. pneumophila* serogroup 13 were included in their evaluation (12), although as illustrated by 2 of our cases, urinary antigen assays will not likely diagnose this specific serogroup in most cases. Furthermore, in the United States, surveillance systems have found that diagnosis of legionellosis by culture, DFA, and serologic testing (IFA) decreased significantly from 1980 to 1998 (11). Nevertheless, in case 2, the DFA of bronchoalveolar lavage fluid was positive to polyclonal antisera. Also in case 1, IFA serology showed seroconversion to *L. pneumophila* serogroup 13–specific antigen. However, serologic diagnosis of *Legionella* infection has only been fully validated for *L. pneumophila* serogroup 1 (14). Thus, the increasing reliance on nonculture–based tests as the sole methods of diagnosing legionellosis is a cause for concern, given the variable utility of these assays.

In most cases, *L. pneumophila* pneumonia is attributed to inhaling contaminated aerosols produced by cooling towers, showers, and nebulizers (1,3,7). Aspiration is also a possible mechanism of transmission (15,16). The source
and reservoir of *L. pneumophila* are generally not identified in sporadic legionellosis (17,18). However, in case 3, the infection was linked epidemiologically and microbiologically with a contaminated spa whirlpool filter. Although legionellosis is well described in association with spa whirlpools (19,20), we are unaware of any previously reported cases of *L. pneumophila* serogroup 13 infections linked to spa whirlpools. Additionally, aspirating water and nearly drowning has a rare but well-recognized association with *L. pneumophila* pneumonia (21–23), although we are unaware of any previously reported cases of *L. pneumophila* serogroup 13 pneumonia after a person’s nearly drowning. For the remaining 2 cases, despite extensive environmental sampling, a source or reservoir of infection was not established. In case 2, after a person’s nearly drowning, investigations failed to find *L. pneumophila* serogroup 13. Serologic diagnosis of *L. pneumophila* serogroup 13 pneumonia has been occasionally reported from New Zealand and Australia, although clinical data from these cases are unreported. Recovery of environmental isolates mainly from soil and water is also reported in this region (24–26).

Serotyping, serogrouping, typing, and subtyping legionellae are technologically challenging. Both phenotypic and genotypic analyses of *L. pneumophila* are required to reliably epidemiologically link patient and environmental isolates. Phenotypic or genotypic studies in higher reference laboratories were performed on our isolates, thereby reliably confirming their identity as *L. pneumophila* serogroup 13. Epidemiologic studies to identify possible sources of legionellosis require careful investigation, including sensitive and discriminatory subtyping techniques to identify similarities and differences between possibly related strains. Methods reported include various panels of monoclonal antibodies, plasmid analysis, RFLPs, ribotyping, macrorestriction enzyme digestion followed by PFGE, and *mip* gene sequencing (27). Recently, Fry et al. have suggested that amplified fragment length polymorphism typing may be the best method for investigating the epidemiology of travel-related legionellosis (28). Newer typing techniques for legionellosis include multilocus sequencing typing and DNA chip technologies (29).

In summary, we describe for the first time in detail the clinical and laboratory features of *L. pneumophila* serogroup 13 infections. *L. pneumophila* serogroup 13 is a rare but perhaps underrecognized pathogenic *L. pneumophila* serogroup. Although the organism was first reported in the United States (5), its global distribution is highlighted here. We found that this organism produces a broad spectrum of clinical disease, from relatively mild disease to severe, potentially fatal pneumonia. Finally, this report emphasizes that culture for *Legionella* species remains important if the prevalence and incidence of legionellosis are to be reliably and fully appreciated.

**Acknowledgments**

We thank Bill Abraham and Diane Lindsay for performing serologic typing and sequencing analysis of the *L. pneumophila* serogroup 13 isolate from case 1; the Australian Legionella Reference Laboratory staff for typing the clinical and environmental isolates relating to case 2; Roslyn Podmore and her team from Canterbury Health Laboratories, who isolated *Legionella* species from the clinical specimens of patients with cases 3 and 4; and Paul Chadwick for reviewing the manuscript.

Dr B. Faris is consultant microbiologist in the Department of Microbiology, Trafford General Hospital. His main research interests are foot infections in patients with diabetes, intravenous antimicrobial home therapy, and multidrug-resistant organisms.
