Appropriate Screening for Leishmaniasis before Immunosuppressive Treatments

To the Editor: We read with great interest the article by Xynos et al. reporting 2 cases of leishmaniasis in patients treated with biologic drugs (1). Although we agree with most of the article, we are not totally convinced that serologic analysis alone could be used to screen for leishmaniasis before initiation of biologic or immunosuppressive treatments. Evidence indicates that serologic analysis can identify only symptomatic or asymptomatic cases with recent and still active infection (2,3).

Leishmania spp. are pathogens that infect hematopoietic cells, where they establish chronic intracellular parasitism and survive for an infected person’s lifetime. In leishmaniasis-endemic countries, asymptomatic visceral leishmaniasis (VL) infections occur more frequently than clinically apparent VL cases. An estimated 10%–20% of persons with asymptomatic infections develop clinically overt VL (4). The leishmanin skin test (LST) (Montenegro test), an intradermal injection of a suspension of killed promastigotes, measures delayed hypersensitivity reactions and appears to be the only screening test capable of detecting asymptomatic leishmaniasis infections.

A positive LST result is thought to indicate durable cell-mediated immunity after asymptomatic infection or clinical cure of VL. LST positivity may appear months to years postinfection, but once positivity appears, it persists in immunocompetent patients. A survey of VL in Ethiopia showed LST positivity in 32.2% of the population, but leishmania antibodies were found in only 4.1% (5).

Because different antigen preparations may affect test sensitivity, LST should use promastigotes of the Leishmania spp. present in an area. We believe that ideal screening for leishmaniasis should include LST along with serologic analysis. Unfortunately, little data exist on the use of antileishmania therapies for LST-positive or serologically positive patients. VL with unusual signs and symptoms may develop in immunocompromised patients with previous LST positivity after immunosuppressive treatments. Information about LST positivity is useful for calling attention to this potential risk for VL that may have unusual manifestations in these persons.

limitations. In a longitudinal study of visceral leishmaniasis in Bangladesh, Bern et al. reported loss of LST sensitivity attributed to antigen-production issues, such as standardization and documentation of sensitivity, potency, and stability of leishmanin antigens (5). Also, prior treatment with immunosuppressive agents, which influence cell-mediated immunity, may decrease LST prognostic potency similarly to changes observed for the tuberculin skin test in similar settings (6).

Variations in specificities and sensitivities limit the diagnostic potential of available diagnostic tools. The context of immunosuppression further contributes to the diagnostic complications and increases the need for additional research in leishmaniasis diagnostics.

ANOTHER DIMENSION

Red Snappers

Erin E. McConnell

for a moment pretend
you are not
the infallible house staff,
but the latest admission—
hacking putrid sputum
from your soulful depths
or your festering chest,
depending on your mood.

slapped with a mask,
you are secured in secluded rooms;
the paucity of guests,
but for the parade of absurd birds—
plastered in Haz-mat
lemon-yellow gowns,
and peach-colored beaks.
your meager dried-up sleep
is aborted by
bloodhungry fowl
covetous of mucus
you no longer produce.

your meals grow cold
waiting for you
in the anteroom of
your negative pressure purgatory.
