Chronic wasting disease (CWD) is a transmissible spongiform encephalopathy, or prion disease, that affects deer, elk, and moose. Human susceptibility to CWD remains unproven despite likely exposure to CWD-infected cervids. We used 2 nonhuman primate species, cynomolgus macaques and squirrel monkeys, as human models for CWD susceptibility. CWD was inoculated into these 2 species by intracerebral and oral routes. After intracerebral inoculation of squirrel monkeys, 7 of 8 CWD isolates induced a clinical wasting syndrome within 33–53 months. The monkeys’ brains showed spongiform encephalopathy and protease-resistant prion protein (PrPres) diagnostic of prion disease. After oral exposure, 2 squirrel monkeys had PrPres in brain, spleen, and lymph nodes at 69 months postinfection. In contrast, cynomolgus macaques have not shown evidence of clinical disease as of 70 months postinfection. Thus, these 2 species differed in susceptibility to CWD. Because humans are evolutionarily closer to macaques than to squirrel monkeys, they may also be resistant to CWD.

Transmissible spongiform encephalopathies (TSEs), or prion diseases, are neurodegenerative diseases that affect many mammalian species. Some examples include bovine spongiform encephalopathy (BSE) in cattle, scrapie in sheep and goats, Creutzfeldt-Jakob disease (CJD) in humans, and chronic wasting disease (CWD) in cervids. CWD was first found in captive deer in Colorado in 1967 (1) and was later identified in several US states and Canadian provinces (2). Epidemiologic evidence suggests that CWD continues to spread among cervid populations in North America (3), creating concern that CWD may cross species barriers to infect humans or domestic animals that may be eaten by humans. Thus, the host range of CWD and the level of protection provided by species barriers should be determined.

Substantial progress has been made in testing species barriers for CWD by using transgenic mice expressing species-specific prion protein (PrP), by direct infection into new species, or by in vitro conversion assays. The most sensitive method for testing susceptibility to TSE agents is intracerebral injection. Unfortunately, this route does not mimic most natural situations and only enables assessment of whether the possibility of transmission exists. Hamir et al. infected cattle and sheep with CWD by the intracerebral route and found protease-resistant PrP (PrPres) in 5 of 13 cattle and 2 of 8 sheep, which indicated that these ruminant species can propagate CWD (4,5). However, oral exposure in these hosts apparently does not cause disease (2).

CWD cross-species transmission to nonagricultural and laboratory animals has shown variable levels of susceptibility depending on the route of transmission. For example, ferrets were 100% susceptible to CWD by intracerebral infection but were not susceptible to oral infection (6,7). Mink were only 25% susceptible to CWD by intracerebral infection and were not susceptible to oral infection.
CWD has been successfully transmitted and adapted to laboratory rodents, including hamsters, transgenic mice expressing hamster PrP, and transgenic mice overexpressing mouse PrP. In contrast, transgenic mice expressing human PrP were not susceptible to CWD by intracerebral infection, a finding that provided evidence for a human species barrier against CWD infection. However, work started in 1980 and published in 2005 by Marsh et al. showed that 2 squirrel monkeys (Saimiri sciureus) infected by the intracerebral route with brain homogenate from a single CWD-affected mule deer became clinically sick at 31 and 34 months postinfection, and both were positive for PrPres. This evidence that at least 1 species of nonhuman primate was susceptible to CWD weakened the conclusion that humans may be protected from CWD by a species barrier.

We addressed 4 questions raised by the original observation that squirrel monkeys are susceptible to CWD. First, we compared intracerebral and oral routes of infection. This comparison was of interest because the oral route is likely to be an important natural route of disease transmission, and susceptibility is known to be lower by this route in most models. Second, we compared 2 species of nonhuman primates, cynomolgus macaques (Macaca fascicularis) and squirrel monkeys, each of which has previously shown susceptibility to various human prion diseases. However, humans are believed to be evolutionarily closer to cynomolgus macaques than to squirrel monkeys, and cynomolgus macaques may be a more accurate model for a human species barrier. Third, because only 1 CWD source was tested by Marsh et al., we studied 8 different pools of CWD representing wild and captive cervids, including mule deer, white-tailed deer, and elk, from separate regions in the United States. Fourth, we tested the species tropism of CWD agent passed in squirrel monkeys.

Materials and Methods

A description of the materials and methods used in this study follows. Additional details are available in the online Technical Appendix, available from www.cdc.gov/EID/content/15/9/1366-Techapp.pdf.

Animal Research

All monkeys and mice were housed at the Rocky Mountain Laboratories (Hamilton, MT, USA). Experimentation followed protocols approved by the National Institutes of Health Rocky Mountain Laboratories Animal Care and Use Committee.

CWD Pools for Infection of Primates

CWD-positive brain homogenates were provided by E.S.W. and M.W.M. Contents of each pool were as follows: MD-1, 6 free-ranging mule deer from Wyoming; MD-2, 4 captive mule deer from Colorado; MD-3, 28 captive mule deer from Wyoming and Colorado; WTD-1, 7 captive white-tailed deer from Wyoming and Colorado; WTD-2, 1 wild white-tailed deer from Wyoming; Elk-1, 2 free-ranging elk from Wyoming; Elk-2, 6 elk from a South Dakota game farm; and Elk-3, 10 captive elk from Wyoming and Colorado. Normal elk brain was a pool from 2 elk from Montana obtained from Lynn Creekmore of the US Department of Agriculture.

Inoculation of Monkeys

For intracerebral injections, squirrel monkeys received either 2 mg or 20 mg brain in a total volume of 200 μL, and cynomolgus macaques received 5 mg in a total volume of 500 μL. Oral doses of 200 mg brain/mL were given on 5 different days at 2–6 day intervals. Squirrel monkeys received 3-mL doses; most macaques received 4-mL doses. The inoculum was given to anesthetized animals through a rubber gastric tube.

Inoculation of Transgenic Mice

Brain homogenates diluted in phosphate buffered balanced solution containing 2% fetal bovine serum were inoculated intracerebrally into young adult mice. Volumes were 50 μL.

Generation of Transgenic Mice Expressing Human PrP

Mice expressing human PrP (tgRM and tg66) were generated by using a transgene, cosSHa.HumPrP, which was created by ligating the human PrP open reading frame into the cosSHa.Tet vector. The transgene was inoculated into eggs of FVB–mouse PrP null mice in the laboratories of R.R. (tg66) and L.C. (tgRM). Each line of mice overexpressed human PrP as tested by Western blot with monoclonal antibody 3F4.

Analysis of Protease-sensitive PrP and PrPres by Immunoblot

Tissues were prepared by making a 20% (wt/vol) homogenate in 0.01 M Tris buffer, pH 7.4. Samples to be analyzed for protease-sensitive PrP (PrPsen) contained the following protease inhibitors: 10 μmol/L leupeptin, 1 μmol/L pepstatin A, and 1 μg/mL aprotinin. Samples were sonicated for 1 min and centrifuged at 5,000 rpm for 10 min. Supernatants were mixed 1:1 in 2× sample buffer and boiled for 3 min before electrophoresis.

Preparation of samples for PrPres analysis has been described. Removal of carbohydrate residues from PrPres was performed by digestion with peptide-N-glycosidase F.

After electrophoresis, proteins were transferred to Immobilon polyvinylidene difluoride–P membranes (Milli-
pore, Billerica, MA, USA), and PrP bands were detected with antibodies 3F4 (residues 109–112) (23), D13 (residues 96–106) (24) (InPro Biotechnology, Inc., South San Francisco, CA, USA), or L42 (residues 145–163) (r-Biopharm, Darmstadt, Germany) (25). Bands were detected by using enhanced chemiluminescence substrate (GE Healthcare, Piscataway, NJ, USA).

**Histopathologic and Immunohistochemical Analyses**

Routine formalin fixation, embedding, and tissue-sectioning protocols were followed. Tissues were stained with hematoxylin and eosin and analyzed for pathologic changes. Immunohistochemical staining was performed by using an automated Nexus stainer (Ventana, Tucson, AZ, USA). Anti-PrP antibodies D13 and 3F4 were used for PrPres immunostaining as described (26,27).

**Sequencing**

Primate genomic DNA was purified from whole blood, and PCR products were amplified by using PuRe Taq Ready-To-Go PCR beads (GE Healthcare). Two primers from the extreme outer ends of the open reading frame, including the previously published forward primer HM-1 (28) with mPrP-780R (5′-TCCCACTATCAGGAAGATGAGG-3′) or a combination of outer primers with internal primers mPrP-397F (5′-CCTTGGTGGCTACATGCTG-3′) and mPrP-416R (5′-CCAGCATGTAGCCACCAAG-3′), were used. Assembly comparisons were made against human, elk, mule deer, cynomolgus macaque, and squirrel monkey by using Sequencher version 4.6 (Gene Codes, Ann Arbor, MI, USA).

**Results**

**Infectivity Levels in CWD Pools**

When the 8 pools of CWD (representing both wild and captive deer and elk) used as inocula were analyzed by immunoblot, PrPres in the 8 pools showed similar electrophoretic mobilities and glycoform patterns (Figure 1, panel A), but PrPres levels differed when quantitatively compared (Figure 1, panel C). To measure the level of infectivity in these pools, we titered each pool in transgenic mice expressing deer PrP (line 33; tgDeerPrP) (18). A typical end-point dilution titration is shown in Figure 1, panel B. The 8 pools had 50% infectious dose (ID₅₀) titers ranging from $6.3 \times 10^7$ to $5.0 \times 10^8$ ID₅₀/g of brain homogenate (Figure 1, panel C). Comparison of titers with PrPres levels showed a partial correlation (Figure 1, panel C). For example, the CWD pool with the lowest infectivity titer (MD-2) was also the pool with the lowest PrPres level. However, for some pools, these tests showed discrepant values.

**Intracerebral Infection of Squirrel Monkeys**

To test susceptibility to CWD, we inoculated squirrel monkeys with each of the 8 CWD pools described above. Of 13 squirrel monkeys, 11 became symptomatic (33–53 mo postinfection [mpi]) (Table 1). The most consistent and reliable clinical finding was a severe wasting syn-
were encouraged to move, they did so slowly and hunched at the bottom of their cage. When the monkeys became weak and less active and spent most of their time continuing to eat and drink. In the final 3–5 weeks, monkeys also had rough, poor-quality coats despite pronounced in the final few months of infection. Affected monkeys also had tremors, excessive salivation, and mild ataxia. Fine, coordinated movement such as eating food was rarely affected. Monkeys were euthanized when terminal-stage weakness and wasting compromised their mobility and ability to eat and drink.

No clear correlation between incubation period and amount of agent inoculated was noted (Table 1). For example, 3 pairs of monkeys received the same inocula but in amounts that differed by 10-fold (Elk-1, Elk-3, and MD-1). Two pairs that received the lower dose became clinically sick first (Elk-1 and Elk-3). Both members of the third pair (MD-1) were euthanized after 36 months (Table 1). Two animals received the same dose of WTD-1 pool, yet to date, only 1 animal has become clinically sick. Animals that received the CWD pool with the lowest titer (MD-1) were euthanized after 36 months (Table 1). Two pairs that received the lower dose became clinically sick (Elk-1 and Elk-3). Both members of the third pair (MD-1) were euthanized after 36 months (Table 1). Two animals received the same dose of WTD-1 pool, yet to date, only 1 animal has become clinically sick. Animals that received the CWD pool with the lowest titer (MD-1) had incubation periods similar to those receiving much higher titered inocula (Table 1).

In all monkeys with clinical signs, CWD was confirmed by Western blot detection of PrPres in brain (Figure 2, panels A, B). The glycoform pattern of PrPres was similar for all affected monkeys inoculated with different CWD pools (Figure 2, panel B). Because PrPres deposition may also occur outside the central nervous system, we also tested peripheral lymphoid tissues. For 3 of 11 monkeys that had PrPres in brain, PrPres was also found in spleen and lymph nodes (Figure 2, panel C). In general, PrPres levels were much lower in lymphoid tissues than in brain and were often not detected by Western blot. All nonlymphatic tissues tested (cardiac muscle, skeletal muscle, duodenum, jejunum, ileum, colon, salivary gland, kidney, and lung) were negative for PrPres by immunoblot.

Tissues from squirrel monkeys euthanized after intracerebral injection with CWD (Table 1) were also examined by histopathologic analysis, including staining with hematoxylin and eosin and immunohistochemical detection of PrPres. All monkeys examined had spongiosis in the cerebral cortex, caudate, putamen, and thalamus (Figure 3, panel A). In addition, PrPres deposition was observed in many brain regions with large PrPres-positive plaques in the thalamus, cerebellum, and spinal cord (Figure 3, panels C, E, F) and in smaller plaques spread out in the gray matter of the internal capsule and white matter of the corpus callosum (Figure 3, panels G, H). The most abundant and consistent location for PrPres staining was found in the frontal cortex and in the fiber tracts of the claustrum (Figure 3, panel I). The adjacent caudate had severe spongiosis and astrocytosis but minimal PrPres (Figure 3, panel I). PrPres was also detected in lymph nodes and spleen, within follicles, in areas resembling follicular dendritic cells (Figure 3, panels K, M). Immunohistochemical analysis showed no PrPres in heart, kidney, adrenal gland, skeletal muscle, salivary gland, tongue, pancreas, white fat, and all regions of the gastrointestinal tract.

**Oral Infection of Squirrel Monkeys**

To test a more natural route of infection, we exposed squirrel monkeys orally to CWD. Of the 15 exposed squirrel monkeys, 1 (no. 345) was found dead in its cage at

drome. Weight loss (average decrease of 33%) was most pronounced in the final few months of infection. Affected monkeys also had rough, poor-quality coats despite continuing to eat and drink. In the final 3–5 weeks, monkeys became weak and less active and spent most of their time hunched at the bottom of their cage. When the monkeys were encouraged to move, they did so slowly and deliberately. In the terminal stage of disease, a few had muscle tremors, excessive salivation, and mild ataxia. Fine, coordinated movement such as eating food was rarely affected. Monkeys were euthanized when terminal-stage weakness and wasting compromised their mobility and ability to eat and drink.

No clear correlation between incubation period and amount of agent inoculated was noted (Table 1). For example, 3 pairs of monkeys received the same inocula but in amounts that differed by 10-fold (Elk-1, Elk-3, and MD-1). Two pairs that received the lower dose became clinically sick first (Elk-1 and Elk-3). Both members of the third pair (MD-1) were euthanized after 36 months (Table 1). Two animals received the same dose of WTD-1 pool, yet to date, only 1 animal has become clinically sick. Animals that received the CWD pool with the lowest titer (MD-1) had incubation periods similar to those receiving much higher titered inocula (Table 1).

In all monkeys with clinical signs, CWD was confirmed by Western blot detection of PrPres in brain (Figure 2, panels A, B). The glycoform pattern of PrPres was similar for all affected monkeys inoculated with different CWD pools (Figure 2, panel B). Because PrPres deposition may also occur outside the central nervous system, we also tested peripheral lymphoid tissues. For 3 of 11 monkeys that had PrPres in brain, PrPres was also found in spleen and lymph nodes (Figure 2, panel C). In general, PrPres levels were much lower in lymphoid tissues than in brain and were often not detected by Western blot. All nonlymphatic tissues tested (cardiac muscle, skeletal muscle, duodenum, jejunum, ileum, colon, salivary gland, kidney, and lung) were negative for PrPres by immunoblot.

Tissues from squirrel monkeys euthanized after intracerebral injection with CWD (Table 1) were also examined by histopathologic analysis, including staining with hematoxylin and eosin and immunohistochemical detection of PrPres. All monkeys examined had spongiosis in the cerebral cortex, caudate, putamen, and thalamus (Figure 3, panel A). In addition, PrPres deposition was observed in many brain regions with large PrPres-positive plaques in the thalamus, cerebellum, and spinal cord (Figure 3, panels C, E, F) and in smaller plaques spread out in the gray matter of the internal capsule and white matter of the corpus callosum (Figure 3, panels G, H). The most abundant and consistent location for PrPres staining was found in the frontal cortex and in the fiber tracts of the claustrum (Figure 3, panel I). The adjacent caudate had severe spongiosis and astrocytosis but minimal PrPres (Figure 3, panel I). PrPres was also detected in lymph nodes and spleen, within follicles, in areas resembling follicular dendritic cells (Figure 3, panels K, M). Immunohistochemical analysis showed no PrPres in heart, kidney, adrenal gland, skeletal muscle, salivary gland, tongue, pancreas, white fat, and all regions of the gastrointestinal tract.

**Oral Infection of Squirrel Monkeys**

To test a more natural route of infection, we exposed squirrel monkeys orally to CWD. Of the 15 exposed squirrel monkeys, 1 (no. 345) was found dead in its cage at
69 mpi; it had shown no neurologic signs or weakness. Western blot results indicated PrPres in brain, spleen, and lymph nodes (Figure 2, panel D). The level of PrPres in the brain of monkey 345 was comparable with that in end-stage intracerebrally inoculated monkeys; body weight at necropsy indicated a 33% decrease over the final 10 months. The high levels of PrPres and the severe wasting indicate that CWD infection could have been the cause of death. A second monkey, 303, was euthanized at 69 mpi because of suspicion of TSE after 2 weeks of progressive weakness, wasting, and eventual anorexia. PrPres analysis confirmed PrPres in brain (Figure 2, panel D), spleen, and lymph nodes. For monkeys 303 and 345, levels of PrPres in the lymph nodes and spleens were 10–100-fold lower than those in brain.

Two other orally infected monkeys were euthanized during the first 69 mpi (Table 2). Monkey 301 was euthanized at 39 mpi, after rapid onset of lethargy and anorexia that led to severe dehydration. Results of Western blot analysis for PrPres were negative in brain (Figure 1, panel B), spleen, lymph nodes, heart, skeletal muscle, duodenum, jejunum, ileum, colon, salivary gland, kidney, lung, and tonsil. However, immunohistochemical analysis detected PrPres in the spleen and 1 mesenteric lymph node from this monkey, indicating a low level of infection (Figure 3, panels J, K). Monkey 614 was euthanized at 44 mpi be-
cause it did not recover from anesthesia related to routine tuberculosis screening. Neither Western blot nor immunohistochemical analysis detected PrPres in brain, spleen, or lymph nodes of this monkey.

Infection of Cynomolgus Macaques

We inoculated cynomolgus macaques both orally and intracerebrally with 3 CWD inocula representing elk, mule deer, and white-tailed deer (Table 3). Of the cynomolgus macaques, 1 (no. 609) was euthanized at 48 mpi after it became aggressive. Brain (Figure 2, panel B), spinal cord, spleen, and lymph nodes were negative for PrPres by Western blot and immunohistochemical analysis. All remaining CWD-inoculated cynomolgus monkeys are currently (at 70 mpi) neurologically asymptomatic and have stable or increased body weights.

Sequences

Amino acid substitutions in PrP can alter susceptibility to TSE agents, including CWD (18, 29, 30). To determine whether the lack of susceptibility in several intracerebrally inoculated squirrel monkeys (Table 1) was caused by PrP gene polymorphisms, we sequenced the PrP genes from 23 squirrel monkeys. When compared with published squirrel monkey sequences (28, 31), variation was seen at residue 164, in the number of octapeptide repeats, and at residue 19 of the signal peptide (Table 4). However, these genetic differences in PrP did not appear to account for the lack of susceptibility of monkey 310, which was genotype A, because this genotype was also found in 5 of the CWD-positive monkeys. Because we were not able to sequence PrP of monkey 628, we could not assess the role of PrP variation in the lack of disease.

Infectivity of CWD-infected Squirrel Monkey Tissues in PrP Transgenic Mice

To determine whether passage of CWD in squirrel monkeys altered the tropism of the infectious agent, we inoculated tgDeerPrP mice and tg mice expressing human PrP (lines 66 and RM) intracerebrally with tissue homogenates from 3 CWD-positive squirrel monkeys (nos. 322, 308, and 301) with PrPres and from an intracerebrally inoculated cynomolgus monkey (no. 609). Clinical disease did not develop in any tgDeerPrP mice during 600–700 days (Table 5). The lack of transmission to tgDeerPrP, tg66, or tgRM mice from the 3 squirrel monkeys with detectable CWD PrPres indicated that either the infectivity levels were low in these squirrel monkeys or that the original cervid species tropism was altered by the passage in squirrel monkeys. Similarly, the lack of transmission to tg mice expressing human PrP implied that passage through squirrel monkeys did not facilitate adaptation to an agent with increased tropism for humans.

†††Monkey 345 was found dead at 69 mpi. Brain, spleen, and lymph nodes were positive for PrPres by Western blot.

Discussion

As new CWD foci continue to emerge among cervid populations, the risk for CWD transmission to humans needs to be assessed. We used 2 monkey species and 2 routes of inoculation to test the susceptibility of primates to 8 different pools of CWD. To date, we have verified CWD in 11 of 13 intracerebrally inoculated squirrel monkeys; average incubation period was 41 months (range 33–53 months). Using a single CWD pool, Marsh et al. noted infection in 2 of 2 squirrel monkeys 31–34 months after intracerebral inoculation (13). Intracerebral inoculation of squirrel monkeys with other TSE agents, including agents of kuru, variant CJD, sporadic CJD, and sheep scrapie, had incubation periods of ≈24 months and attack rates of ≈100% (14,15,32). The extended incubation periods and lower attack rates for our squirrel monkeys may result from a partial species barrier to CWD.

The signs of wasting syndrome in CWD-infected monkeys were similar to those of CWD infection in cervids, in which loss of body condition is nearly always a major component of infection and neurologic deficits vary (2). The correlation of clinical signs between CWD in cervids and squirrel monkeys suggests that CWD might affect a common brain region in each species. We observed PrPres deposition in squirrel monkeys primarily in the frontal lobe of the cerebral cortex, claustrum, putamen, and thalamus. Cervids typically have the most abundant and predictable PrPres in the dorsal motor vagus nucleus (obex), olfactory cortex, and diencephalon (including thalamus, hypothalamus, metathalamus, and epithalamus) (2,33). A plausible

*CWD, chronic wasting disease; mpi, months postinfection; NA, not available.
†Infectivity titers were determined by using endpoint dilution titer in transgenic deer expressing mouse prion protein and are listed as the total 50% infectious dose/g of brain.
‡Monkey 609 was euthanized at 48 mpi, and no protease-resistant prion protein was detected by Western blot or immunohistochemical analysis.
hypothesis could be that disruption of regions within the hypothalamus and thalamus leads to a metabolic imbalance, resulting in a severe wasting syndrome. We did not observe a strong correlation between infectivity titer inoculated and attack incidence or incubation period (Table 1). One potential explanation is that the variation in speed of disease progression might not be relevant given the low number of animals in each group. A second possibility is that our squirrel monkeys varied at PrP alleles that may affect CWD susceptibility. However, analysis of 23 squirrel monkeys showed no PrP sequence differences correlating with susceptibility to CWD (Tables 1, 2, 4). A third possibility is that genes other than the gene for PrP might influence CWD susceptibility.

For humans, eating infected or contaminated tissue is a likely route of CWD exposure. In other animal models, oral transmission of TSE is generally 1,000-fold less effective than direct intracerebral challenge and results in longer incubation periods and lower efficiency of disease transmission. In our oral transmission experiments, we found evidence of CWD infection in 3 monkeys; 2 at 69 mpi had abundant PrPres in brain and lower levels in spleen and lymph nodes, and 1 euthanized at 39 mpi had PrPres in lymphatic tissues only. Thus, transmission seems to be slower by the oral route than by the intracerebral route, and other orally infected monkeys may be affected in the future.

Cynomolgus macaques are evolutionarily closer to humans than are squirrel monkeys (17). At nearly 6 years postinoculation, no macaques have shown clinical signs of CWD. Intracerebral inoculation of cynomolgus macaques with BSE causes disease in 3 years; human variant CJD requires 2–3 years, and human sporadic CJD requires 5 years (16,34). However, oral inoculation of cynomolgus macaques with BSE agent required a minimum of 5 years before clinical disease was observed (35). There-

†PrP, prion protein; ND, not determined.
‡The PrP genes of 23 monkeys were sequenced, and 3 genotypes were found. For easy reference to Tables 1 and 2, they are designated types A, B, and C. Previous squirrel monkey PrP sequences were identified by Schätzl et al. (28) and Schneider et al. (31).
§According to published sequences, PrP genotype variations were seen only at residue 19 (in the signal peptide), residue 164, and in the number of octapeptide repeats.

†CWD, chronic wasting disease; PrP, prion protein; TSE, transmissible spongiform encephalopathy; NT, not tested; sCJD, sporadic Creutzfeldt-Jakob disease.
‡Each donor monkey inoculum was prepared as a 1% brain homogenate from the indicated monkeys. SM, squirrel monkey; CM, cynomolgus macaque. Elk and mule deer CWD inocula were described in Materials and Methods. Human sCJD inocula are brain homogenates from World Health Organization CJD reference materials. No. 99–009 is sCJD M/M type I, and no. 97–008 is sCJD M/M type II. The RR sample was from a patient with sCJD of unknown PrP genotype. The PLG sample (M/M type I) was from a patient with sCJD. In all cases except sCJD (RR), 50 μL was inoculated intracerebrally into recipient mice; for sCJD (RR), 30 μL was inoculated.
§Based on Western blot or immunohistochemical analysis of brain for all except monkey 301, in which protease-resistant PrP (PrPres) was detected in spleen but not brain.

1373
fore, we cannot rule out CWD transmission to cynomolgus macaques.

The PrP gene sequence can influence cross-species transmission of prion disease. Therefore, we compared squirrel monkey and cynomolgus macaque PrP gene sequences to look for differences that might account for different susceptibilities of these monkeys to CWD. In the PrP gene excluding the signal peptide, deer differed from squirrel monkeys at 17 residues and from cynomolgus macaques at 16 residues, but 14 of these differing residues were identical in squirrel monkeys and macaques (Figure 4). Therefore, there are only 2 residues in cynomolgus macaques (100 and 108) and 3 residues in squirrel monkeys (56, 159 and 182) at which these monkeys differ from deer and also from each other. These residues might play a role in susceptibility differences seen in our study.

Human exposure to CWD-infected cervids in past decades is likely. The highest levels of prion infectivity are present in the central nervous system and lymphatic tissues of CWD-infected cervids; contamination of knives, saws, and muscles with these tissues can easily occur when processing game. Despite the likelihood of exposures, epidemiologic studies of humans living in CWD-endemic areas of Colorado and Wyoming during 1979–2001 have not shown any increases in human TSE cases (36,37). Ongoing studies by the Colorado Department of Public Health and Environmental Human Prion Disease Surveillance Program, in conjunction with the University of Colorado School of Medicine, have also concluded that no convincing cases of CWD transmission to humans have been detected in Colorado (38). However, if CWD in humans appears like a wasting syndrome similar to that observed in the squirrel monkeys in our study, affected persons might receive a diagnosis of a metabolic disorder and never be tested for TSE. Fortunately, additional laboratory data are consistent with the epidemiologic data, and these results support the conclusion that a species barrier protects humans from CWD infection (11–13,20,36,37).

Acknowledgments

We thank John Portis, Byron Caughey, and Kristin McNally for critical review of the manuscript; Lori Lubke and Rebecca Rosenke for assistance with histologic analysis; Rocky Rivera and Ed Schreckendgust for animal husbandry; Anita Mora and Gary Hettrick for graphics assistance; Serguei Soukharev for assistance in creating transgenic mice expressing human PrP; Robert Rohwer for tg66 mice and sporadic CJD inocula; Terry Kreeger, Jean Jewell, and Lynn Creekmore for CWD-positive and CWD-negative cervid tissues; and Pier-Luigi Gambetti for a sample from a patient with sporadic CJD.

This study was supported by the National Institute of Allergy and Infectious Diseases, Division of Intramural Research.

Figure 4. Comparison of prion protein sequences from various species. The following species are shown, and GenBank accession numbers are given when available: human (M13899), cynomolgus macaque (Cyno Mac) (U08298), squirrel monkey (Sq Mk) (genotype RML-A, see Table 4), squirrel monkey from Schneider et al. (31) (AY765385), squirrel monkey from Schätzl et al. (28) (U08310), mule deer (AY330343), and elk (AF156183). Numbering is based on the human sequence. Gray boxes indicate residues different from human residues. Alignment of the sequences was conducted with MegAlign software (DNASTAR/Lasergene, Madison, WI, USA).
Dr Brent Race is a staff scientist in the Laboratory of Persistent Viral Diseases, National Institute of Allergy and Infectious Diseases. His primary research interests are infectious diseases of humans and livestock, especially transmissible spongiform encephalopathies.

Susceptibilities of Nonhuman Primates to Chronic Wasting Disease

Technical Appendix

Materials and Methods

Nonhuman Primates

All monkeys were housed individually at the Rocky Mountain Laboratories (RML) (Hamilton, MT, USA) in a facility accredited by the Association for Assessment and Accreditation of Laboratory Animal Care International (Frederick, MD, USA). Experimentation followed protocols approved by the National Institutes of Health RML Animal Care and Use Committee. All monkeys were included in a nonhuman primate enrichment program that included housing in which they could view others in the colony and toys and treats for psychological well-being. Initially, 12 cynomolgus macaques (age range 3–9 years) were obtained from the RML breeding colony, and 3 were obtained from the Mauritius Islands off the coast of Africa through Primate Products, Inc. (Miami, FL, USA). Imported animals were screened for tuberculosis, B virus (cercopithecine herpesvirus 1), herpes simplex virus 1, measles, simian retrovirus, and simian immunodeficiency virus. Cynomolgus macaques were fed Hi-Protein Monkey Diet (Nestle Purina Petcare Co., St. Louis, MO, USA) augmented with fresh fruit and monkey treats (Bio-Serv, Frenchtown, NJ, USA). All squirrel monkeys were obtained from Guyana, South America, through Worldwide Primates (Miami, FL, USA). These animals were screened for tuberculosis, saimirine herpesviruses, measles, and cytomegalovirus. Squirrel monkeys were fed a combination primate diet (Nestle Purina Petcare Co. and ZuPreem, Shawnee, KS, USA) augmented with fresh fruit. Water was provided ad libitum to all monkeys in the study.

CWD Pools for Infection of Primates

MD-1 is a pool from 6 free-ranging mule deer from Wyoming and was published as deer-2 (1). MD-2 is a pool from 4 captive mule deer from Colorado identified by the Colorado Department of Wildlife as 03 407541, 03 465081, 03 464506, and 03 460516. MD-3 is a pool
from 28 captive mule deer from Wyoming and Colorado (2,3), also referred to as deer-3 (I) and md-PrP<sub>CWD</sub> (4).

WTD-1 is a pool from 7 captive white-tailed deer from Colorado and Wyoming, published as deer-1 (I) and wtd-PrP<sub>CWD</sub> (4). WTD-2 is from 1 wild white-tailed deer from Wyoming. Elk-1 is a pool from 2 free-ranging elk from Wyoming published as elk (I). Elk-2 is a pool from 6 elk (nos. 98W615, 98W618, 98W2542, 98W9292, 98W9527, and 99W2206) from a South Dakota game farm. Elk-3 is a pool from 10 captive elk obtained from Colorado and Wyoming.

Normal elk brain was a pool from 2 animals from Montana, MTKS no. 37 and MTKS no. 49 (MTKS37/49), obtained from Lynn Creekmore of the U.S. Department of Agriculture. CWD pools MD-1, MD-3, WTD-1, WTD-2, Elk-1, Elk-2, and Elk-3 were contributed in full or in part by E.S.W., and pools MD-2, MD-3, WTD-1 and Elk-3 were contributed in full or in part by M.W.M.

Inocula were prepared by homogenizing brain tissue in 0.01 M Tris-HCl, pH 7.4, by using a sterile glass dounce with 10 strokes or until no clumps were visible. Pooled samples were combined in a 100-mL graduated cylinder on ice and adjusted to 20% wt/vol. Homogenates were vortexed and then sonicated for 2 min. For intracerebral infection, samples were cleared by centrifuging at 2,000 rpm for 5 min. Supernatants were frozen at −80°C until needed. Before infection, samples were thawed in a 37°C water bath, sonicated for 1 min, and diluted in phosphate-buffered balanced salt solution containing 2% fetal bovine serum to achieve concentrations needed for intracerebral inoculations.

**Inoculation of Monkeys and Mice**

For intracerebral inoculations, squirrel monkeys received either 2 mg or 20 mg brain in a total volume of 200 μL, and cynomolgus macaques received 5 mg in a total of 500 μL volume. The diluted brain homogenate was injected into a surgically created hole in the skull over the left parietal lobe of anesthetized animals.

Oral doses of 200 mg brain/mL were given on 5 different days at 2–6 day intervals. Squirrel monkeys received 3-mL doses; most macaques received 4-mL doses. Three macaques inoculated with WTD-1 received 3-mL doses. The inoculum was given to anesthetized animals
through a rubber gastric tube that was flushed with Tris-buffered saline (TBS) before removal from the stomach.

Intracerebral inoculations into the parietal lobe of anesthetized young adult mice were conducted by using tissue homogenates diluted in phosphate-buffered balanced salt solution containing 2% fetal bovine serum. Volumes were 50 μL unless otherwise indicated.

**Titration and Passage of CWD Infectivity in Transgenic Mice**

The 8 cervid pools were titered by endpoint dilution with serial 1:10 dilutions of brain homogenate ranging from $10^{-2}$ (1%) to $10^{-8}$. Dilutions were inoculated intracerebrally into transgenic mice expressing deer PrP (line 33) (1). For all other inoculations into transgenic mice expressing deer or human PrP, a $10^{-2}$ dilution was used. The volume inoculated was 50 μL for all homogenates except for the sporadic CJD inoculum used in the tg66 mice, which was 30 μL.

Mice were observed for clinical signs for >600 days (Figure 1, panel B). Mice with clinical signs were euthanized, and a diagnosis of CWD was confirmed by immunoblot detection of PrPres. End-point titer was determined by using the Spearman-Karber method (5). Briefly, the following formula was used: 50% infectious dose (ID<sub>50</sub>) = $x_p = 1 + 1/2d - d\sum p$ where $x_p = 1$ is the highest log dilution giving all positive responses, $d$ is the log dilution factor, $p$ is the proportion positive at a given dose, and $\sum p$ is the sum of values of $p$ for $x_p = 1$ and all higher dilutions. When 10-fold dilutions were used, the error with this method was ±0.5 logs. The log value for the ID<sub>50</sub> was converted to scientific notation for all figures and tables in this report.

**Generation of Transgenic Mice Expressing Human PrP**

Mice expressing human PrP were generated by using a transgene, cosSHa.HumPrP, which was created by ligating the human PrP open reading frame (ORF) into the cosSHa.Tet vector (6). Full-length human PrP ORF from human DNA was generated as an 803-bp PCR product by using the forward and reverse primers 5’-TGAGCGGCCGCGCAGTCATTATGGCGAACCTTG-3’ and 5’-TACTGAGTCGACCCCTTCTCATCCCACATCAGG-3’. The PrP ORF was cloned into pGEM-5zR+ after digestion with NotI and SalI. Sequence analysis confirmed the human PrP sequence. Addition of a Kozak translation initiation site and cloning into the cosSHa.Tet vector was performed by using techniques similar to those described (7). The transgene was inoculated into eggs of FVBn– mouse PrP null mice in the laboratories of R.R. and L.C. We used...
homzygous tg66 mice and hemizygous tgRM mice. These mice overexpress human PrP as tested by Western blot with monoclonal antibody 3F4. When compared with Tg7 hamster PrP–expressing mice, tg66 mice had 5–10× overexpression and tgRM mice had 1–2× overexpression. We did not have any human brain tissue for direct comparison with human PrP expression, but antibody 3F4 is known to react with human and hamster PrP.

Analysis of PrPres by Immunoblot

Tissues were prepared by making a 20% (wt/vol) homogenate in ice cold 0.01 M Tris buffer, pH 7.4, by using either an Omni Tissue homogenizer with disposable hard tissue probe (Omni International, Marietta, GA, USA) or a pestle in a DNase/RNase–free 1.5-mL tube (Kontes Glass Co., Schenectady, NY, USA). Samples were sonicated for 1 min and kept frozen until analyzed. Samples to be analyzed for protease-sensitive PrP were prepared as above with addition of the following protease inhibitors: 10 μmol/L leupeptin, 1 μmol/L pepstatin A, and 1 μg/mL aprotinin. After sonication, samples were centrifuged at 5,000 rpm for 10 min, and supernatants were mixed 1:1 in 2× sample buffer and boiled for 3 min. Preparation of samples for PrPres analysis has been described (18). Briefly, 20 μL of a 20% (wt/vol) tissue homogenate without protease inhibitors was adjusted to a concentration of 100 mmol/L Tris-HCl, pH 8.3, 1% Triton X-100, and 1% sodium deoxycholate in a total volume of 31 μL. Samples were treated with 50 μg/mL of proteinase K for 45 min at 37°C. The reaction was stopped by adding 2 μL of 0.1 M phenylmethylsulfonyl fluoride, and samples were placed on ice for 5 min. An equal volume of 2× Laemmeli sample buffer (Bio–Rad, Hercules, CA, USA) was added, and samples were boiled for 5 min.

Removal of carbohydrate residues from PrPres was performed by digestion with PNGaseF (8). Briefly, 20 μL of PrPres samples in 2× Laemmeli sample buffer were boiled for 10 min, and 2 μL of 10× G7 buffer and NP40 and 2 μL of PNGase F were added. Samples were incubated overnight at 37°C and kept frozen at −20°C until analyzed by immunoblotting.

Samples were subjected to electrophoresis on a 16% sodium dodecyl sulfate–polyacrylamide gel, and proteins were transferred to Immobilon polyvinylidene difluoride–P membranes (Millipore, Billerica, MA, USA). PrP bands were detected with antibodies 3F4 (residues 109–112) (9), D13 (residues 96–106) (10) (InPro Biotechnology, Inc., South San Francisco, CA, USA), or L42 (residues 145–163) (r-Biopharm, Darmstadt, Germany) (11).
Membranes were incubated in primary antibody (diluted 1:5,000) in TBS-T for 1.5 hours, rinsed with TBS–Tween (TBS-T) buffer, and incubated with their appropriate horseradish peroxidase–conjugated secondary antibody (sheep anti-mouse immunoglobulin [Ig] G for 3F4 and L42, sheep antihuman IgG for D13) at a 1:5,000 dilution in TBS-T for 30 min. Bands were detected by using enhanced chemiluminescence substrate as recommended by the manufacturer (GE Healthcare, Piscataway, NJ, USA).

**Histopathologic and Immunohistochemical Analyses**

Tissues were placed in 3.7% phosphate-buffered formalin for 3–5 days before dehydration and embedding in paraffin. Serial 4-μm sections were cut by using a standard microtome (Leica Microsystems Inc., Bannockburn, IL, USA), placed on a positively charged glass slide, and dried overnight at 56°C. Sections were stained with hematoxylin and eosin and analyzed for pathologic changes. Immunohistochemical staining was performed by using an automated Nexus stainer (Ventana, Tucson, AZ, USA). Slides were deparaffinized and rehydrated in Tris-HCl, pH 7.5. Staining for antibodies against PrP was conducted by using antibodies D13 and 3F4 against PrP as previously described (12,13).

**Sequencing**

Primate genomic DNA was purified from whole blood by using the QIAamp DNA Blood Maxi Kit (QIAGEN, Valencia, CA, USA) as directed. PCR products were amplified by using PuRe Taq Ready-To-go PCR beads (GE Healthcare). Two primers from the extreme outer ends of the ORF, including the previously published forward primer HM-1 (14) with mPrP-780R (5’-TCCCCACTATCAGGAAGATGAGG-3’) or a combination of outer primers with internal primers mPrP-397F (5’-CCTTGGTGCGCTACATGCTG-3’) and mPrP-416R (5’-CCAGCATGTAGCCACCAAG-3’), were used. Three successful amplicons were generated and purified by using the QIAquick PCR (QIAGEN) as recommended and sequenced by using their respective forward and reverse PCR primers on an ABI 3730xl instrument (Applied Biosystems, Inc., Foster City, CA, USA). Sequence data were stored in the FINCH data management system (Geospiza, Seattle WA, USA). Assembly comparisons were made against human, elk, mule deer, cynomolgus macaque, and squirrel monkey by using Sequencher version 4.6 (Gene Codes, Ann Arbor, MI, USA).
