**Paenibacillus larvae Bacteremia in Injection Drug Users**

Siegbert Rieg, Tilman Martin Bauer, Gabriele Peyerl-Hoffmann, Jürgen Held, Wolfgang Ritter, Dirk Wagner, Winfried Vinzenz Kern, and Annerose Serr

*Paenibacillus larvae* causes American foulbrood in honey bees. We describe *P. larvae* bacteremia in 5 injection drug users who had self-injected honey-prepared methadone proven to contain *P. larvae* spores. That such preparations may be contaminated with spores of this organism is not well known among pharmacists, physicians, and addicts.

As a consequence of needle sharing and repeated parenteral administration of nonsterile material, injection drug users risk becoming ill from a variety of infections, including HIV, hepatitis C, endocarditis, and skin and soft tissue infections (1). Febrile episodes in injection drug users are common, yet distinguishing between febrile reactions caused by toxins or impurities in the injected substance and true infections may be difficult (2,3). Methadone hydrochloride, which is widely used for opioid substitution, can be mixed with viscous substances such as syrup to yield a solution that is not suitable for misuse through self-injection. Methadone syrup is intended to be taken only as an oral medication. Some pharmacies use honey instead of syrup to prepare such a solution.

*Paenibacillus larvae* is a spore-forming gram-positive microorganism known for its ability to cause American foulbrood, a severe and notifiable disease of honey bees (*Apis mellifera*) (4) (Figure). *P. larvae* is endemic to bee colonies worldwide. The organism can be cultured from <10% of honey samples from Germany but from >90% of samples from honeys imported from other countries (5). *P. larvae* spores are highly resilient and can survive in honey for years (6,7). We describe *P. larvae* bacteremia in 5 patients who had a history of intravenous drug abuse and were in a program of opioid substitution that used methadone.

**The Study**

All patients sought treatment for fever ranging from 37.8°C to 39.8°C and admitted to continuing to inject illicit drugs or methadone. Information about patient characteristics, clinical signs and symptoms, laboratory and microbiologic investigations, and treatment details are summarized in the Table. *P. larvae* was identified in blood cultures (BacT/ALERT 3D-System; bioMérieux, Marcy l’Etoile, France) of each patient described. The clinical course of *P. larvae* bacteremia was benign in 3 patients, and complications developed in 2 patients. Patient 1 had relapsing disease and spontaneous bacterial peritonitis; patient 4 had pulmonary embolism without definite evidence of septic embolism. Patients 2 and 3 recovered without specific antimicrobial drug treatment; for patients 4 and 5, defervescence and negative follow-up blood cultures were observed after they received treatment with β-lactam agents (imipenem or cefuroxime). The recurrent *P. larvae* infection observed in patient 1 was probably the consequence of repeated injection of contaminated methadone rather than an inadequate response to antimicrobial drug therapy.

In 2 cases, culture of the honey used to prepare methadone or of honey-containing ready-to-use methadone also yielded *P. larvae*. Honey and methadone samples were diluted in sterile phosphate-buffered saline and cultured with or without heat pretreatment (90°C, 10 min) under aerobic and anaerobic conditions at 37°C for 3–4 days by using Columbia blood agar and MYPGD (Mueller-Hinton broth, yeast extract, potassium phosphate, glucose, pyruvate) agar. Colonies from positive blood or honey or methadone cultures with an appropriate macroscopic appearance and gram-stain morphology as well as negative catalase reaction were further identified by PCR amplification and 16S rRNA gene sequencing according to published protocols (8). Obtained sequences were analyzed by using the BLAST algorithm (http://blast.ncbi.nlm.nih.gov/Blast.cgi).

**Conclusions**

We detected *P. larvae* in sterile compartments of 5 patients with clinical and laboratory evidence of infection. Given the fact that all patients were injection drug users, the mode of infection was thought to be intravenous administration of contaminated methadone, resulting in *P. larvae* bacteremia. Our hypothesis is supported by the isolation of *P. larvae* from honey or honey-containing methadone provided to 2 patients.

Recently, several *Paenibacillus* species have been reported to cause bacteremic infections in humans. Among these are *P. thiaminolyticus* (bacteremia in a patient undergoing hemodialysis) (9), *P. konsidensis* (bacteremia in a febrile patient with hematemesis) (10), *P. alvei* (prosthetic joint infection with bacteremia) (11), and *P. polymyxa* (bacteremia in a patient with cerebral infarction) (12). Further-
more, the novel species *P. massiliensis*, *P. sanguinis*, and *P. timonensis* were isolated from blood cultures of patients with carcinoma, interstitial nephropathy, and leukemia, respectively (13). Pseudobacteremia of *P. hongkongensis* and *P. macerans* has been reported (14,15).

Several aspects provide strong evidence for a genuine *P. larvae* bacteremia in the cases described here. First, the present cases were observed over a period of several years, and detection of *P. larvae* thus occurred in different charges of blood culture bottles, which argues against pseudobacteremia. Second, isolation of *P. larvae* was reported independently by 2 microbiology laboratories, making contamination highly unlikely. Third, in patient 1 isolation succeeded at different times and in samples of different compartments. Moreover, the detection of *P. larvae* in honey-prepared methadone and honey strongly suggests genuine bacteremia as a consequence of injection of contaminated material.

Biochemical and molecular identification of *P. larvae* may be difficult and time-consuming. Misinterpretation of blood culture results because of incomplete differentiation or confusion with other gram-positive spore forming-bacteria (e.g., *Bacillus* species) has to be taken into consideration. Underestimation of the frequency of true *P. larvae* bacteremia therefore cannot be excluded. Thus, infectious disease physicians, microbiologists, and pharmacists need to be aware that injection of material contaminated with *P. larvae*, such as honey-prepared methadone, may cause bacteremic infection.

Dr Rieg is an infectious diseases fellow at the University Medical Center in Freiburg, Germany. His research interests focus on innate defense antimicrobial peptides and *Staphylococcus aureus* infections.
