Mycobacterium conceptionense Infection after Breast Implant Surgery, France

To the Editor: Mycobacterium fortuitum complex members are rapidly growing mycobacteria found in water and soil (1). These opportunistic pathogens are responsible for posttraumatic soft and tissue infections. They also account for 60%–80% of postsurgical wound infections caused by rapidly growing mycobacteria (2), particularly after breast surgery (with or without prosthetic implants) (3). M. conceptionense, an emerging member of the M. fortuitum complex, was initially described in a case of osteomyelitis that occurred after an open fracture of the tibia (4). We report a case of M. conceptionense infection that occurred after breast surgery.

A woman 58 years of age had a left mastectomy with lymph node dissection and chemotherapy for breast carcinoma in March 2004. Three years later, she underwent breast reconstruction that used a cutaneomuscular latissimus dorsi flap with a prosthetic implant. Immediately after surgery, a fever (39°C) developed, but 3 blood cultures remained sterile. No treatment was administered, and she became afebrile within 3 days.

At day 15 after surgery, a serous discharge appeared in the tip of the skin flap. By day 21, the patient was again febrile, and the wound discharge was swabbed for analysis. On day 27, she underwent surgical revision with ablation of the breast implant, drainage, and sample collection. The leukocyte count was normal. However, the C-reactive protein level was 99 mg/L, and the erythrocyte sedimentation rate was 111 mm (first hour). Treatment with intravenous amoxicillin/clavulanic acid was started. Although the biologic parameters normalized, the serous discharge continued. Microscopic examination of specimens from days 21 and 27 yielded no bacteria in Gram- and Ziehl-Nielsen–stained pus specimens, and standard bacteriologic cultures remained sterile. M. conceptionense, identified by partial rpoB gene sequencing (100% identity with GenBank accession no. AY859695.1) (4), grew in both specimens after 8 days of incubation at 37°C under a 5% CO2 atmosphere in Coletsos medium (bioMérieux, La Balme-les-Grottes, France). By the Etest method (4), both isolates were susceptible to several antimicrobial drugs, including clarithromycin, amikacin, ciprofloxacin, and doxycycline. The patient was treated with ciprofloxacin, azithromycin, and amikacin for 3 weeks, followed by ciprofloxacin and azithromycin for 4 weeks.

At patient’s relapse 3 months later, M. conceptionense exhibiting identical antimicrobial drug susceptibility pattern was again isolated from the wound fluid. The patient was then treated with ciprofloxacin, azithromycin, and doxycycline for 6 months; subsequently, doxycycline alone was given for a total of 18 months. Results from the 2-month follow-up examination were unremarkable.

M. conceptionense was unambiguously identified by partial rpoB gene sequencing, a first-line tool for accurate identification of nontuberculous mycobacteria (5). A pathogenic role for M. conceptionense was supported by 1) its repetitive isolation from the wound;
2) the absence of any other pathogen; and 3) wound healing during appropriate, long-term antimicrobial drug treatment. However, the source of infection remained unknown. The patient had a tattoo on the skin flap used for the breast reconstruction, and ink has been shown to be a source for rapidly growing mycobacteria other than M. conceptionense (6). However, the tattoo was 5 years old and clinically safe.

Recent reports have identified 12 M. conceptionense isolates from water collected in a cooling tower (7) and 9 isolates from various freshwater fish species (8). The type strain of M. conceptionense had been isolated after prolonged exposure of the patient to fresh water (4). These observations suggest that water is a potential source for M. conceptionense. In this patient, use of contaminated aqueous solutions or inadequately rinsed surgical equipment (9) was unlikely the source of infection because further investigations indicated proper use of sterilized, non-reusable surgical equipment. At home, the patient used well water, but results of tests used to detect M. conceptionense by culture and the presence of the rpoB gene in well water remained negative.

Because M. conceptionense is an emerging pathogen with only 2 reported cases of infection (4,10), the optimal treatment is unknown (Table). Current recommendations for breast implant infection from M. fortuitum include 6 months of appropriate antimicrobial drug treatment in addition to implant removal because surgery alone yields relapse within 4–6 weeks (2,3). Increased worldwide use of breast implants is likely to increase the number of M. conceptionense infections and will raise questions about the optimal management of these infections.

Rapid Diagnostic Tests and Severity of Illness in Pandemic (H1N1) 2009, Taiwan

To the Editor: The recent pandemic (H1N1) 2009 (1) demonstrates the need for more sensitive rapid diagnostic tests (RDTs) to distinguish between influenza and other respiratory viruses, enhance influenza surveillance, and institute early antiviral therapy for patients who are severely ill or at high risk (2). In anticipation of the global spread of pandemic (H1N1) 2009, on August 15, 2009, the government of Taiwan began performing RDTs at clinics and hospitals for patients with influenza-like illness. This initiative was based in part on the notion that patients with higher viral loads would be more likely to have a positive RDT result and more severe disease. We report that RDTs may have paradoxically lower sensitivity for pandemic (H1N1) 2009 virus for patients with respiratory failure requiring mechanical ventilation, extracorporeal membrane oxygenation (ECMO) or both than for those without respiratory failure.

National Taiwan University Hospital is a 2,200-bed teaching hospital in Taiwan. This hospital provides primary and tertiary care and ECMO. All patients admitted with presumed severe influenza were immediately treated with oseltamivir during the 2009 pandemic. From July 25 through
