Identification of Legionella feeleii Cellulitis

To the Editor: In general, reports of extrapulmonary Legionella spp. infections are scarce. For example, L. micdadei infection was found with the following manifestations: a mass on the left side of the neck and low-grade fever in a healthy 9-year-old girl (1); multiple liver and lung abscesses in a 7-year-old girl with acute lymphoblastic leukemia who had undergone allogeneic cord blood transplantation (2); and a cerebral abscess in a patient with legionellosis (3).

L. feeleii was first described in 1984 as the causative agent of a Pontiac fever outbreak (4). L. feeleii was responsible, according to a recent review, for only 10 reported cases of infections, all of which were pneumonitis, only 1 complicated by endocarditis (5). Unlike lung abscesses, cutaneous lesions caused by Legionella spp. are uncommon. Recurrent soft tissue abscesses of the jaw, wrist, and arm caused by L. cincinnatiensis were described in a 73-year-old woman with nephrotic syndrome and idiopathic immunoglobulin gammopathy (6). L. micdadei has been found in a cutaneous abscess of the leg of a 62-year-old immunosuppressed woman, and it was responsible for necrotizing cellulitis that resulted in amputation of the left arm of a recipient of a cadaveric renal transplant (7). L. pneumophila with mixed flora was identified in a rectal abscess (8) and in skin samples from a patient with lymphoma and cellulitis associated with pneumonia (9). The infrequency of reporting Legionella spp. cutaneous infections may be explained in part by the fact that Legionella spp. agar is not routinely a part of media inoculated for cases of cutaneous abscess. Here we report the identification of L. feeleii in a cutaneous infection through the use of a shell vial culture protocol.

In late October 2009, a 66-year-old woman was admitted to Hôpital Nord, Marseille, France, for a papular lesion complicated by cellulitis and an abscess, centered on her right leg (Figure). The patient’s history noted that she had been bitten by an insect or spider (suspected to be a spider) on October 9. The next day, the patient had a fever of 39°C, and a papular lesion appeared around the bite. Four days later, the fever had persisted, and she was given amoxicillin-clavulanate and local wound care. Two days later, the lesion became necrotic, and levofloxacin was added to the medication regimen. At day 10 after the bite, cellulitis with a central abscess appeared on her leg. The patient was transferred to Hôpital Nord. At admission, she had leukocytosis (16.9 × 10⁹ cells/L) with neutropenia (0.51 × 10⁹ cells/L), slight anemia (104 g/dL), and in anemia (104 g/dL), and inflammatory syndrome (C-reactive protein 72 mg/L, erythrocyte sedimentation rate 150 mm after 1 h); she was also still febrile (38°C). She had a history of chronic lymphocytic leukemia. A cutaneous biopsy sample showed inflamed and necrotic tissue, which suggested squamous cell evoking carcinoma.

Gram staining of tissue samples did not show any bacteria, and conventional cultures incubated under aerobic and anaerobic conditions did not lead to growth after 3 weeks of incubation. Je ne sais pas (or “I don’t know [what I’m growing]” [10]) shell vial culture protocol was done on a skin biopsy sample of the lesion. Culturing was performed by the centrifugation shell vial technique with 3.7 mL human embryonic lung fibroblast cell monolayers (Sterilin, Felthan, UK) inoculated with the skin biopsy sample previously triturated in cell culture medium. Small extra- and intracellular bacilli were observed directly inside the shell vial by using Gimenez and Gram staining. DNA extraction, partial 16S rRNA gene amplification and sequencing, and mip and rpoB gene amplification and sequencing were done on shell vial supernatant. Partial sequence of 16S rRNA identified a Legionella sp. Subsequently, L. feeleii was identified with 100% and 96.5% sequence similarity for mip and rpoB genes, respectively. The biopsy sample was unfrozen and then injected onto Legionella spp.–buffered charcoal yeast extract agar as the supernatant.
tantal of the shell vial. No growth was obtained from the biopsy sample, but L. feelli was identified similarly from colonies growing on buffered charcoal yeast extract agar plates injected with shell vial supernatant. The patient’s necrotic tissues were surgically excised; a vacuum-assisted closure system was used. Reexamination of the tissue biopsy samples ruled out the diagnosis of carcinoma.

Finally, despite the fact that the shell vial technique requires specialized equipment and trained personnel, this method was performed in a reference center to improve the accuracy of a microbiologic diagnosis and, consequently, the care of the patient in uncommon situations (10). This improvement in diagnosis and care was also noted in an unusual L. pneumophila infection described by our team (2).

In our laboratory, we have been performing the je ne sais pas protocol almost routinely since 1996 (10). Cell cultures provide supplemental tools to elucidate the cause of microbial diseases when results of PCR and classical agar procedures are negative. Furthermore, this procedure provides a means for the isolation of a wide range of intracellular bacteria, even when little biopsy material is available.

Sparganosis, Henan Province, Central China

To the Editor: Sparganosis is a parasitic zoonosis caused by invasion of the sparganum, the plerocercoid larvae of various diphyllobothroid tapeworms belonging to the genus Spirometra (1). Although human sparganosis is cosmopolitan, it is most frequently found in eastern and southeastern Asia (2). During 1927–2009 in the People’s Republic of China, >1,000 cases in humans in 27 provinces were reported; most cases were in southern China, where human infections were mainly acquired by eating raw or insufficiently cooked meat of frogs and snakes or by placing frog or snake flesh on open wounds for treatment of skin ulcers or on eyes to treat inflammation (3,4).

Sparganosis is rarely seen in central and northern China. Before 2006, only 3 imported cases from southern China had been reported in Henan Province in central China (5). However, since 2006 in Henan Province, 20 autochthonous cases caused by ingestion of live tadpoles have emerged. To assess the risk for human infection with sparganosis in this province and to strengthen public safety awareness, we investigated spargana infection in the animal hosts of Spirometra tapeworms.

During July 2007–July 2010, wild frogs and frog tadpoles were collected from the cities of Shangqiu, Zhoukou, and Luoke in Henan Province. Necropsies identified plerocercoids in 11.93% (163/1,366) of tadpoles and in 26.58% (172/647) of frogs. By frog species, plerocercoids were found in 31.09% (111/357) of R. nigromaculata species than in R. temporaria species (4).
