*Plasmodium knowlesi* can cause severe malaria in adults; however, descriptions of clinical disease in children are lacking. We reviewed case records of children (age <15 years) with a malaria diagnosis at Kudat District Hospital, serving a largely deforested area of Sabah, Malaysia, during January–November 2009. Sixteen children with PCR-confirmed *P. knowlesi* monoinfection were compared with 14 children with *P. falciparum* monoinfection diagnosed by microscopy or PCR. Four children with knowlesi malaria had a hemoglobin level at admission of <10.0 g/dL (lowest minimum level 6.4 g/dL). Minimum level platelet counts were lower in knowlesi than in falciparum malaria (median 76,500/μL vs. 156,000/μL; p = 0.01). Most (81%) children with *P. knowlesi* malaria received chloroquine and primaquine; median parasite clearance time was 2 days (range 1–5 days). *P. knowlesi* is the most common cause of childhood malaria in Kudat. Although infection is generally uncomplicated, anemia is common and thrombocytopenia universal. Transmission dynamics in this region require additional investigation.

The simian malaria parasite *Plasmodium knowlesi* is increasingly recognized as a frequent cause of potentially fatal human malaria in adults in Malaysian Borneo (1–4). The infection has also been reported in peninsular Malaysia (5) and in other Southeast Asian countries, including Thailand (6,7), Myanmar (8,9), Vietnam (10), the Philippines (11), Indonesian Borneo (12–14), and Singapore (15,16). Until recently, *P. knowlesi* had been almost uniformly misdiagnosed by microscopy as *P. malariae* because of its morphologic similarities, leading to underestimations of prevalence (1,17). Accurate diagnosis therefore requires molecular methods.

The clinical and laboratory features of *P. knowlesi* infections in adults have been described in Kapit, Sarawak, where 107 (70%) of 152 adults with malaria were infected with *P. knowlesi* (3). Although *P. knowlesi* malaria was diagnosed in 8 children, the clinical and laboratory features were not described. All previously reported *P. knowlesi* infections that caused clinical disease have been in adults (1,2,6,8,11–13,15,18–20). In malaria caused by *P. falciparum* (21) and *P. vivax* (22), the 2 species that cause the greatest number of human malaria cases, well-described differences exist between adults and children in terms of the clinical epidemiology, disease spectrum, and laboratory manifestations of disease. We report the demographic, clinical, and laboratory features of *P. knowlesi* infection in children in Kudat, Sabah, a rural coastal farming area with little remaining primary rainforest, an epidemiologic setting that contrasts with the previously described forested areas of Sarawak.

**Methods**

**Study Setting**

The study was conducted at Kudat District Hospital (KDH) on the northeast tip of Sabah, Malaysia, a coastal rural area which has been largely deforested. KDH services 5 subdistricts (Tigapapan, Dualog, Matunggung, Tambuluran, and the island of Banggi), with a total population of 85,000 persons. The Rungus are the most
common ethnic group on the mainland, and minority groups include ethnic Chinese, Bajaus, Dusuns, and Balabaks.

Ministry of Health policy in Sabah requires that all patients with a blood film result that indicates malaria be admitted to the hospital and discharged only after smear results are negative for 2 consecutive days. Since January 2009, in response to increasing reports of \( P. \) knowlesi infections and the difficulties of diagnosing this species by microscopy, it became policy at KDH to send slides that had been determined by microscopy to show presence of \( P. \) malariae to the Sabah State Reference Laboratory for PCR confirmation. In addition, KDH sends \( \approx15\% \) of all blood films positive for other \( Plasmodium \) spp. for PCR confirmation.

**Retrospective Case Review**

We retrospectively searched laboratory microscopy records for all blood smear results positive for \( Plasmodium \) spp. during January 1–November 30, 2009. The patient’s age, sex, ethnicity, and address were recorded for all positive samples. Microscopy results were matched with PCR results.

Medical records were retrieved for all children <15 years of age who had received a diagnosis of malaria on the basis of microscopy results. Demographic, clinical, and laboratory details were extracted by using standardized data forms, which also included disease response to antimalarial treatment. Parasite clearance time was defined as the number of days until negative smear. Anemia and severe anemia were defined as hemoglobin levels <11 g/dL and <7.1 g/dL, respectively.

**Laboratory Procedures**

Blood films were examined by experienced laboratory microscopists at KDH with the parasite count being classified in most on a scale of 1 to 4 (1 = 4–40 parasites/\( \mu \)L, 2 = 41–400 parasites/\( \mu \)L, 3 = 401–4,000 parasites/\( \mu \)L, 4 = >4,000 parasites/\( \mu \)L), with accurate quantitation per microliter being recorded for most blood films that showed \( P. \) knowlesi, but for only a limited number that showed \( P. \) falciparum. Hemoglobin level and leukocyte and thrombocyte counts were measured on site by using automated systems (Sysmex XT1800 [Sysmex Corp., Mundelein, IL, USA] and CELL-DYN Sapphire [Abbott Diagnostics, Abbott Park, IL, USA]) At the Sabah State Reference Laboratory, parasite DNA was extracted, and nested PCR was performed for \( P. \) falciparum, \( P. \) vivax, \( P. \) malariae, \( P. \) ovale, and \( P. \) knowlesi by methods described (1,23).

**Statistical Analysis**

Data were analyzed by using Stata statistical software, version 10 (StataCorp LP, College Station, TX, USA). Proportions were compared by using the \( \chi^2 \) or Fisher exact test. Normally distributed and non–normally distributed variables were compared by using Student's t test and Wilcoxon rank-sum test, respectively. For comparison between \( P. \) falciparum and \( P. \) knowlesi cases, the analysis included children with PCR-confirmed \( P. \) knowlesi infection, and children with \( P. \) falciparum infection diagnosed by either microscopy or PCR. Children with mixed \( Plasmodium \) infections were excluded from analysis, as were children whose medical records could not be located.

**Results**

**Malaria in All Age Groups**

From January 1 through November 30, 2009, 220 patients at KDH were given a diagnosis of malaria on the basis of microscopy results (Figure 1). Of these, 196 (89\%) had \( P. \) malariae monoinfection or mixed infection. PCR was performed on samples from 157 (80\%) of these patients and results were positive for \( P. \) knowlesi in 137 (87\%); 125 (91\%) of these were \( P. \) knowlesi monoinfections. For the remaining 20 patients who had been given a diagnosis of \( P. \) malariae monoinfection or mixed infection by microscopy, PCR found undifferentiated \( Plasmodium \) spp., negative results for \( Plasmodium \) spp., and 7 cases of \( P. \) falciparum infection.

To estimate the final numbers of malaria species, we used positive PCR results when possible and microscopy results when PCR had not been performed (replacing \( P. \) malariae with \( P. \) knowlesi). Microscopy results were also used if PCR result was negative (5 \( P. \) knowlesi infections and 1 \( P. \) knowlesi/\( P. \) falciparum infection) or if PCR result was positive for \( Plasmodium \) spp. (7 \( P. \) knowlesi infections). Using this method, we found 172 (78\%) \( P. \) knowlesi monoinfections, 29 (13\%) \( P. \) falciparum monoinfections, and 19 (9\%) mixed infections (Figure 1). A greater proportion of patients with \( P. \) knowlesi malaria were male (123/172 [72\%]) than were those with \( P. \) falciparum malaria (15/29 [52\%; \( p = 0.03 \)). Median age was higher for those with \( P. \) knowlesi infection (median 32 years, interquartile range [IQR] 19–49 years) than for those with \( P. \) falciparum infection (median 11 years, IQR 6–30 years).

**Malaria in Children**

Of 220 patients with positive results by microscopy, 41 (19\%) were <15 years of age. Microscopy showed that 24 (59\%) children had \( P. \) malariae monoinfection, 10 (24\%) had \( P. \) falciparum monoinfection, and 7 (17\%) had mixed infections (Figure 2). Samples from 17 children with \( P. \) malariae monoinfection underwent PCR; 16 (94\%) showed \( P. \) knowlesi, and 1 showed mixed \( P. \) knowlesi/\( P. \) vivax infection. Again, final numbers of malaria species were
estimated by using PCR results (if available) or microscopy (if PCR had not been performed). Accordingly, 24 cases (59%) were \( P. \) knowlesi, 15 (37%) were \( P. \) falciparum, and 2 were mixed \( P. \) knowlesi/\( P. \) vivax infections. Children thus represented 14% (24/172) of all cases of \( P. \) knowlesi monoinfection.

Further analysis was confined to those children with PCR-confirmed \( P. \) knowlesi monoinfection and children with \( P. \) falciparum monoinfection diagnosed by either microscopy or PCR. Medical records were unavailable for 2 children (1 with \( P. \) knowlesi and 1 with \( P. \) falciparum infection), leaving 16 children with PCR-confirmed \( P. \) knowlesi infection and 14 with \( P. \) falciparum infection for comparison (Table 1).

**Demographic Characteristics of Children with \( P. \) knowlesi Malaria**

Half of the children with PCR-confirmed \( P. \) knowlesi malaria were male (Table 1). The mean age was 8.9 (95% confidence interval 7.6–10.3) years. The youngest child with \( P. \) knowlesi infection was 4 years; all others (15/16; 94%) were 7–14 years of age. In contrast, children with \( P. \) falciparum malaria were significantly younger, with a mean age of 5.4 years (95% confidence interval 3.5–7.3; range 9 months–11 years; \( p = 0.002 \)).

**Clinical Features of \( P. \) knowlesi and \( P. \) falciparum Malaria**

All children had fever or a history of fever. The duration of fever before hospital admission appeared shorter with knowlesi malaria than with falciparum malaria (median 4 days vs. 6.5 days), although this difference was not statistically significant. Although documentation of clinical features was limited, no child was in a state of shock, and no child was reported to be dyspneic, to have bleeding complications, or to have any other clinical feature or laboratory results that indicated severe malaria (24). None of the children who had either knowlesi or falciparum malaria died.

**Anemia**

In 11 (69%) children with \( P. \) knowlesi malaria, the parasite density was accurately determined at hospital admission, with a median of 2,240 (IQR 480–7,200) parasites/\( \mu \)L. Only 2 children with \( P. \) falciparum malaria had parasite densities accurately determined at admission (200 and 1,600 parasites/\( \mu \)L). Anemia was common with \( P. \) knowlesi and \( P. \) falciparum infections. At admission, 9 (56%) children with \( P. \) knowlesi infection were anemic (hemoglobin level <11.0 g/dL), and 4 (25%) had a hemoglobin level <10 g/dL. All children with \( P. \) knowlesi infection had a hemoglobin minimum level <11.0 g/dL, and 10 (63%) had a hemoglobin minimum level <10 g/dL. The lowest hemoglobin level was found in an 8-year-old boy: 8.3 g/dL at admission, 6.4 g/dL on day 3, and 7.2 g/dL on day 6, the day before discharge. His parasite count at

*IQR, interquartile range. Boldface indicates statistical significance.

admission (14,400 parasites/µL) was the highest recorded in this study.

In addition, severe anemia (hemoglobin 6.0 g/dL at admission; minimum level 4.9 g/dL on day 1 requiring transfusion) occurred in a second child with positive results for P. knowlesi by microscopy (this child was not included in the final analysis because of lack of PCR confirmation). Among children with P. knowlesi infection, a lower hemoglobin minimum level was associated with higher parasite density at admission (p = 0.001). All children with P. falciparum infection had hemoglobin levels at admission <11.0 g/dL; 10 (71%) had hemoglobin levels <10 g/dL, and 5 (36%) had severe anemia (hemoglobin <7.1 g/dL). Severe anemia developed in a sixth child after admission. Four children received transfusions, with hemoglobin levels of 4.8–6.1 g/dL at admission. Children with P. knowlesi malaria took longer to reach their hemoglobin minimum level than did children with P. falciparum malaria (2.6 vs 1.5 days; p = 0.02).

Thrombocytopenia

All children with P. knowlesi malaria had thrombocytopenia. Fifteen children (94%) had a platelet count <150,000/µL at admission, and the remaining child exhibited thrombocytopenia within 1 day. The lowest platelet count recorded was 28,000/µL. Platelet count was not correlated with hemoglobin level. Thrombocytopenia was less common in children with P. falciparum; 7 (50%) had platelet counts <150,000/µL at admission or during hospitalization, and the lowest platelet count was 47,000/µL. Children with P. knowlesi malaria had a lower lymphocyte count minimum than those with P. falciparum malaria (1.6 vs. 2.4 ×10³/µL; p = 0.01).

Response to Treatment

Most (81%) children with P. knowlesi malaria were given oral chloroquine and primaquine for 3 days, and these children had a median parasite clearance time of 2 days (Table 2). The longest parasite clearance time with chloroquine and primaquine was 5 days in the aforementioned 8-year-old boy with the highest admission parasitemia level (14,400/µL) and the lowest minimum hemoglobin level (6.4 g/dL). Three children with P. knowlesi infection were given oral quinine, and parasites cleared within 2 days. Among the 11 children with P. knowlesi and parasite densities accurately assessed at admission, the correlation between parasite density and parasite clearance time was significant (p = 0.002).

Children with P. falciparum malaria were given a variety of treatment regimens. Most (71%) received a regimen that contained quinine, 7 (50%) children received sulfadoxine/pyrimethamine, 6 (43%) received primaquine, and 5 (36%) were given chloroquine. Only 5 (36%) received artemisinin-based combination therapy. Parasite clearance times were significantly slower among children with P. falciparum malaria, with a median of 5 days until the first negative smear; in 4 children (29%), it took >10 days for parasites to be cleared. Children with P. knowlesi malaria had significantly shorter hospital admissions (median 4 days, IQR 4–5 days) than did
children with *P. falciparum* malaria (median 7 days, IQR 5–10 days).

**Discussion**

*P. knowlesi* was the most common cause of malaria in adults and children in the Kudat region in Sabah, Malaysian Borneo. Although those with *P. knowlesi* infections had an older age distribution than did those with *P. falciparum* infections, the species still caused 63% of all malaria cases among children <15 years. Although nearly all previous reported cases of knowlesi malaria have been in adults, 14% of all knowlesi cases in Kudat occurred in children. In children, *P. knowlesi* most often caused uncomplicated malaria, which responded well to chloroquine. Nevertheless, knowlesi malaria was associated with substantial illness in children, with all PCR-confirmed *P. knowlesi*-infected children being anemic at admission or during hospital stay.

In the only other report of knowlesi malaria in children, a prospective study of adult knowlesi malaria in Sarawak reported the exclusion of 8 children <15 years with *P. knowlesi* infection, comprising 7% of all knowlesi cases (3). The clinical and laboratory features of *P. knowlesi* malaria in children have not been described. Consistent with the reported features of *P. knowlesi* malaria in adults (3), the disease in most children was uncomplicated. In adults with knowlesi malaria, increasing age is a risk factor for severe disease. Although the numbers are small, none of the children had severe manifestations of knowlesi malaria that have been reported in adults (3), such as acute lung injury or acute renal failure. In falciparum malaria, these conditions are also largely confined to adults (21); anemia, coma, and acidosis-related respiratory distress are the major manifestations of severe falciparum malaria in children. No child with knowlesi malaria exhibited coma or respiratory distress; however, anemia developed in all children with knowlesi malaria, with the hemoglobin concentration in 1 patient (6%) falling to <7.0 g/dL. Anemia was more common in children than has been previously described in knowlesi malaria in adults (3).

Thrombocytopenia was found at admission in nearly all (94%) children with *P. knowlesi* malaria, in contrast to only half of the children with *P. falciparum* malaria. Although the cause is unclear, thrombocytopenia is also nearly universal in infected adults (3), which makes it a characteristic feature of *P. knowlesi* infection across all age groups. The role of thrombocytopenia and platelet activation in the pathogenesis of knowlesi malaria requires further investigation.

Most children with *P. knowlesi* malaria had an adequate response to a 3-day regimen of treatment with chloroquine and primaquine, although the mean parasite clearance time of 2 days was longer than the 90% parasite clearance time of 10.3 hours that was recently reported in adults (25). One child who received chloroquine and primaquine, and had a high parasite count at admission, required 5 days to clear parasites. Standard Ministry of Health pediatric dosing regimens of chloroquine are used in Kudat; however, posttreatment vomiting or inadequate blood concentrations could not be excluded. Prospective studies that evaluate the response to chloroquine and artemisinin-based combination

therapy in pediatric knowlesi malaria are required. Children with *P. falciparum* malaria received many different treatment regimens and took significantly longer to clear their parasites. Less than half received the recommended artemisinin-based combination therapy, and only after alternative treatments failed. Children with *P. falciparum* malaria had significantly longer hospital stays, likely related at least in part to suboptimal treatment regimens. This finding highlights the importance of increasing the usage of artemisinin-based combination therapy for falciparum malaria in district hospitals in Sabah and elsewhere.

Our study had several limitations. First, PCR was only performed for 73% of cases across all age groups, and this limited our ability to accurately determine the true proportion of disease caused by *P. knowlesi*. Furthermore, although PCR was performed on samples from most children with *P. knowlesi* malaria, only 1 child with *P. falciparum* malaria had PCR performed. Our analysis, therefore, compared children with PCR-confirmed knowlesi malaria to children with falciparum malaria diagnosed by either microscopy or PCR. Some of those children with a diagnosis of falciparum malaria may have actually had knowlesi malaria, and the differences found between these 2 species may therefore be minimum estimates. The retrospective design of our study also limited our ability to collect standardized clinical information.

This study demonstrates that *P. knowlesi* has become the predominant malaria species in the Kudat region, estimated by results of microscopy, PCR, or both, as contributing to 87% of all malaria cases, a higher proportion than that reported elsewhere in Malaysian Borneo. The emerging dominance of *P. knowlesi* in Malaysian Borneo has been hypothesized to result from the following factors: changing patterns of human exposure to monkeys and vectors (26) because of deforestation, and potentially reduced competition or cross-species protection from *P. vivax* and *P. falciparum* as a result of a 40-fold reduction in the prevalence of these species in Sabah and Sarawak during 1960–2006 following intensive malaria control efforts (27). The paucity of *P. vivax* in Kudat was particularly notable.

Previous reports of adult disease have been from communities adjacent to rainforests (3). Kudat is a coastal rural farming area with varied land use and vegetation patterns and with minimal remaining regrowth forest. Although our retrospective study did not gather detailed travel or exposure histories, it is likely that most pediatric infections were locally acquired and that infections with *P. knowlesi* did not occur solely in those spending time in forested areas. Macaque monkeys, the natural hosts of *P. knowlesi*, are widely distributed in different habitats throughout the Kudat area and are frequently domesticated. The major vectors of *P. knowlesi* in forested areas of Sarawak, *Anopheles latens* mosquitoes, disappear with deforestation, but vectors capable of transmitting *P. knowlesi*, *An. balabacensis* mosquitoes (26), do persist at lower densities in largely deforested areas of Sabah (28,29). In notable contrast to *P. falciparum* malaria, pediatric knowlesi malaria was restricted to children of school age. Further studies will be required to characterize the transmission patterns, vectors, and risk factors for *P. knowlesi* in deforested areas of Malaysia.

**Conclusions**

*P. knowlesi* is the most common cause of malaria in adults and children in the Kudat region of Sabah, a rural coastal deforested region. Consistent with previous studies in adults (3), we found that *P. knowlesi* in children most often caused uncomplicated malaria that responded adequately to chloroquine and primaquine. Anemia was common in children and knowlesi infection was associated with moderately severe anemia. Thrombocytopenia was universal and is characteristic of knowlesi malaria across all age groups. Larger prospective clinical studies are needed to describe more fully the epidemiology of *P. knowlesi* malaria in children, the full spectrum of clinical disease and the transmission patterns in nonforested areas such as Kudat.
