The availability of a measles vaccine in the 1960s led to substantial reductions in the incidence of measles globally. Along with improvements in living conditions, nutrition, and the availability of antimicrobial drugs for secondary bacterial infections, the mortality rate was greatly reduced (1). A live-attenuated measles vaccine was introduced to Taiwan in 1968, and a routine vaccination policy was established in 1978 to provide measles vaccine to infants at 9 and 15 months of age. During 1992–1994 and 2001–2004, two catch-up campaigns were implemented, targeting birth cohorts September 1976 to September 1990 and September 1990 to September 1994, respectively. Starting in 2006, the measles, mumps, and rubella (MMR) vaccine targeted infants 12–15 months old and 6-year-old children. The coverage rates for the first dose of measles vaccine and the second dose of MMR were 91% and 95%, respectively, since 1996. In recent decades in Taiwan, 4 major measles outbreaks have occurred, with 2,219 (in 1985), 1,386 (1988), 1,060 (1989), and 303 (1992) reported cases. Beginning in 1993, the annual number of reported measles cases was <100; by the end of 2007, the annual number of confirmed measles cases was <10 (2). The ability to actively control measles has increased in Taiwan since 1991 because of a combined plan to eliminate polio, measles, congenital rubella syndrome and neonatal tetanus.

The key to controlling measles is achieving and sustaining high levels of vaccination coverage. Finding a way to prevent the transmission of measles is an important topic for any country in the elimination phase. Here, we report several measles outbreaks that occurred in Taiwan during 2008 and 2009.

The Study

In total, 140 suspected measles cases were reported to the Taiwan Centers for Disease Control from November 2008 to May 2009, and 53 were confirmed (online Appendix Table, www.cdc.gov/EID/content/17/8/100800-appT.htm). The criteria for confirming cases included laboratory diagnosis and establishing an epidemiologic link to the laboratory-diagnosed case. The criteria for the laboratory diagnosis included the presence of measles immunoglobulin (Ig) M, isolation of measles virus, or identification of measles virus by reverse transcription PCR (2,3).

A timetable for occurrence of the 53 measles cases was constructed (Figure 1, panel A) on the basis of the week of onset of rash for each patient. The locations of the hospitals that reported these cases are shown in Figure 1, panel B.

Cluster 1 involved nosocomial infections in hospital A (case-patients 1–5) and hospital B (case-patients 6–8); the transmission between case-patient 5 and case-patient 6 was through household contact. The index case-patient (case 7) was discovered later. Cluster 2 (case-patients 9–21) caused nosocomial infections in hospitals C (case-patients 9–10) and D (case-patients 10–17 and 19). Case-patient 18 was reported by hospital F, case-patient 20 from clinic b and case-patient 21 from hospital O. With the exception of case-patient 20, who attended kindergarten with case-patient 19, there was no exposure linkage between case-patients 18 and 21; the phylogenetic data (Figure 2) did, however, indicate the patients were infected with related strains. Cluster 3 involved case-patients 22–24; the index case-patient (case 7) was discovered later. Cluster 2 (case-patients 25–33) caused nosocomial infections in hospital F (case-patients 25 and 27–33), and case-patients 25 and 26 attended the same school. Cluster 5 (case-patients 34–35) was a nosocomial infection in hospital G. Cluster 6 involved 10 cases: the index case-patient, case 37, was reported by hospital I. Case-patients 36–43 were from the same military base, and case-patients 37, 44, and 45 were relatives. Cluster 7 caused nosocomial infections in hospital H (case-patients 46 and 47) as well as household transmissions (case-patients 47 and 48). Cluster 8 (case-patients 49 and 50) was transmitted by contact at a dormitory. Case-patient 51 had a sporadic case from an unidentified source; case-patients 52 and 53 had sporadic cases linked to importation from Vietnam and India, respectively.

Of these 53 patients with confirmed measles, 36 (67.9%) were male. There were 15 children (28.3%) <12 months of age and 19 children (35.8%) from 12 months to 6 years of age. Adults accounted for 19 cases (35.8%). Only 1 patient (1.88%) had received 2 doses of a measles-containing vaccine; 4 patients (7.5%) had received 1 dose; 7 patients (13.2%) recalled having received vaccines; 9
adults (17.0%) did not know their vaccination status; and
the remaining 31 patients (58.4%) had not received any
vaccines. Among the 6 nosocomial measles outbreaks,
2 infection sources (clusters 2 and 5) were children <12
months old and therefore not eligible for the first dose of
the MMR vaccine, 4 clusters (clusters 1, 3, 4, and 7) were
caused by children between 13–17 months old who were
not vaccinated, and 1 cluster (cluster 8) was caused by an
adult from Vietnam with an uncertain vaccination history.
The outbreak on the military base was caused by an adult
who was assumed to have been vaccinated.

Phylogenetic analysis determined that the measles virus
genotypes from these 8 outbreaks fell into 6 clades (Figure
2). Although the source was untraceable, the measles
virus sequences from cluster 6 belonged to genotype G3;
the sequence was 100% identical to a G3 strain (MVi/H
Kajang.MYS/11.09) isolated from Malaysia (T. Tran, pers.
comm.). The other sequences all belonged to genotype H1
and were grouped into 5 lineages. Clusters 1, 2, and 3 were
linked to importation from the People’s Republic of China
and were grouped into different lineages. Clusters 4, 5, 7,
and 8, which originated in Vietnam, were divided into 2
lineages, with clusters 4, 7, and 8 in the same lineage and
cluster 5 in another lineage.

Conclusions
Among these 53 confirmed cases, 26 (49%) patients
contracted measles from hospital exposure, and 3 patients
(5.7%) were hospital staff. Vaccination policies for workers
in health care institutes should be strengthened because
these workers have the highest potential risk of contracting
the disease (4,5). Many other febrile exanthematic
diseases caused by pathogens other than measles virus,
such as enterovirus, rubella virus, parvovirus B19,
human herpesvirus-6, or Kawasaki syndrome, could have
symptoms similar to measles and be misdiagnosed (6–8).
It is therefore vital to ensure that clinicians are fully aware of
the disease and can recognize it in a timely manner.

After import-associated measles outbreaks were
recognized, the MMR vaccination was recommended for

Figure 1. A) Timetable of 53 measles cases
reported in Taiwan from week 45 of 2008 to week
21 of 2009. Each cell in the timetable represents 1
case; each case is identified with an identification
number followed by a letter that represents the
hospital (uppercase) or clinic (lowercase) that
reported the case. Cases 1–8, 9–21, 22–24,
25–33, 34–35, 36–45, 46–48, and 49–50 belong
to clusters 1 through 8, respectively, and cells
within a cluster are the same color. Cases
51–53 were from 3 sporadic cases and are not
colored. The case numbers peaked during the
eighth week of 2009, with 8 cases distributed
through northern (hospital D), central (hospital
E), and southern (hospitals F and P) Taiwan;
these cases originated from 4 importation chains.
B) Locations of hospitals involved in measles
outbreaks. *Hospital was involved in nosocomial
transmission.

DISPATCHES
Imported Measles, Taiwan, 2009

persons planning to travel to measles-endemic countries. Successful immunization policies that include routinely vaccinating children with 2 doses of a measles-containing vaccine greatly reduce disease contraction among preschool and primary school children (9–11). Because measles outbreaks may occur in areas with high vaccine coverage (12–14), the higher proportion of measles cases in adults, especially in young adults, should be addressed further and evaluated with regard to the possible need for additional immunizations.

The major threats to measles control in Taiwan are similar to those faced by other countries in the elimination phase; the key questions are 1) how to detect the index case in real time, and 2) how to prevent import-associated transmission. Among these continuous outbreaks, 6 chains originated from children <18 months of age without adequate immunization who had recently traveled to measles-endemic countries. Clinicians being alert for patients being brought for treatment with a fever and rash at pediatric clinics will greatly improve the sensitivity of measles surveillance systems and prevent further nosocomial transmission. Special emphasis should be paid to pediatric patients without vaccination records and with a history of travel abroad. Of course, the ultimate goal of eliminating measles requires an agreement from all countries to contain the disease in their own territories.

Acknowledgments

We thank Chan-Hsien Chiu, Tsui-Feng Li, Yi-Chun Wu, Li-Jen Lin, and Ding-Pin Liu for their support and guidance.

This work was supported by the Centers for Disease Control, Taiwan.

Ms Cheng is an associate researcher at Centers for Disease Control Taiwan. She is in charge of laboratory diagnosis of measles, rubella, mumps, and varicella-zoster virus infection. Her research interests involve the changing epidemiology of vaccine-preventable diseases.
