Oral Transmission of Atypical L-type Bovine Spongiform Encephalopathy in Primate Model

Nadine Mestre-Francés, Simon Nicot, Sylvie Rouland, Anne-Gaëlle Biacabe, Isabelle Quadrio, Armand Perret-Liaudet, Thierry Baron, and Jean-Michel Verdier

We report transmission of atypical L-type bovine spongiform encephalopathy to mouse lemurs after oral or intracerebral inoculation with infected bovine brain tissue. After neurologic symptoms appeared, transmissibility of the disease by both inoculation routes was confirmed by detection of disease-associated prion protein in samples of brain tissue.

Transmissible spongiform encephalopathies, also known as prion diseases, are fatal neurodegenerative disorders that affect humans and animals. An atypical form of bovine spongiform encephalopathy (BSE) was recently identified in cattle in Europe (1,2), North America (3), and Japan (4). This atypical BSE was designated L-type BSE (L-BSE) because Western blot analysis showed that the disease-associated protease-resistant prion protein (PrPres) was of lower apparent molecular mass than in the agent of classical BSE, which is involved in the major foodborne epizooty in cattle and in variant Creutzfeldt-Jakob disease in humans (5).

Evidence from experimental studies in primate models (6,7) and transgenic mice expressing human prion protein (PrP) (8,9) suggests that the rare and putatively sporadic form of L-BSE (L0) presents a higher risk than classical BSE for transmission to humans. However, a major unresolved issue is whether L-BSE can be transmitted by the oral route. To address this issue, we inoculated gray mouse lemurs (Microcebus murinus), a nonhuman primate model, by the oral and intracerebral (IC) routes with the agent of L-BSE.

The Study

A total of 12 mouse lemurs of both sexes (Center for Breeding and Experimental Conditioning of Animal Models, University Montpellier 2, Montpellier, France) were maintained in animal Biosafety Level 3 facilities, according to requirements of the French ethics committee (authorization CE-LR-0810). Young and adult lemurs were fed (8 animals) or IC inoculated (4 animals) with 5 or 50 mg of L-BSE–infected brain tissue (10% homogenate in 5% glucose) (Table). The isolate for the L-BSE agent (02–2528) was derived from cattle in France (11). When progression of prion disease was evident, the lemurs were euthanized and their brains were isolated. Brains were processed for Western blot analysis with SHa31 monoclonal antibody against PrP for PrP^res detection, as described in mice (11); for histologic examination by using hematoxylin and eosin staining; and for disease-associated prion protein (PrP^d) immunohistochemical detection by using the paraffin-embedded tissue blot method or immunohistochemical analysis with monoclonal antibody 3F4 against PrP.

Beginning ≈3 months before the terminal stage of the disease (19–22 months after inoculation), neurologic symptoms developed in the 4 mouse lemurs that received IC inoculations (Table). In all 4 animals, initial clinical signs and symptoms were blindness, thigmotaxic behavior, and poor appearance of the fur. Appetite and general fitness were maintained; anxiety and aggressiveness were not observed. Next, locomotion became slower, followed by incoordination and loss of balance in the last month of life. Ipsilateral circling behavior was reported, indicating unilateral degeneration of the striatum. This behavior stopped 15 days after onset, suggesting damage to the contralateral striatum. Disequilibrium, with frequent falls, became more noticeable. At the terminal stage of the disease, the animals were prostrate.

One orally inoculated lemur, which was fed 5 mg of infected brain and euthanized 27 months later, had signs and symptoms of disease similar to those in IC-inoculated animals, except for the ipsilateral circling behavior. In 2 lemurs fed 50 mg and 2 others fed 5 mg of L-BSE–infected brain, clinical signs and symptoms of prion disease developed just a few weeks before the animals were euthanized (18 and 32 months and 33 and 34 months after inoculation, respectively). Disease was characterized by progressive prostration, loss of appetite, and poor appearance of the fur, without incoordination or disequilibrium. The 3 remaining lemurs were orally...
inoculated at 2 years of age and were still alive and healthy
28 months after inoculation (Table).

PrP<sub>res</sub> was readily detected by Western blot analysis
in brain extracts (thalamus/hypothalamus region) from
8 of the 9 animals examined (Table), although at lower
levels in the lemur that was euthanized earlier (i.e.,
18 months after inoculation). Western blot analyses showed
uniform PrP<sub>res</sub> molecular profiles, irrespective of the route
or dose of inoculation, with a low apparent molecular
mass (≈19 kDa, similar to the PrP<sub>res</sub> in the original cattle
brain) (Figure 1). However, the PrP<sub>res</sub> profile in mouse
lemurs was characterized by a higher proportion of di- and
monoglycosylated species (>95% of the total signal) than
in the inoculum of the agent of bovine L-BSE (≈80%). In
addition, PrP<sub>res</sub> was detected by Western blot in the spleens
of 3 (1 IC inoculated and 2 fed with 5 mg of cattle brain) of
the 9 animals examined (Figure 1).

Histopathologic analysis showed severe spongiform
changes in the brains of the 4 IC-inoculated mouse lemurs
(Figure 2, panel A). The brains displayed a pattern of
vacuolation characterized by intense spongiosis with many
confluent vacuoles in the basal telencephalon (septum,
striatum, caudate putamen nuclei), midbrain (thalamus,
hypothalamus), mesencephalon (colliculi), and in some
parts of the brainstem (tectal ventral area, raphe
nuclei). Lesions in the cortex and hippocampus were less
severe than in the subcortical areas. Cerebellum showed
occasional small-size vacuoles. Among the 5 orally
inoculated animals, 2 (1 fed 5 mg, the other fed 50 mg)
showed histopathologic features similar to those observed
in IC-inoculated animals. In the other 3 orally inoculated
animals, spongiosis was characterized by fewer vacuoles
and was restricted to the striatum (Figure 2, panel B),
thalamus, colliculi, and brainstem.

Distribution of PrP<sub>d</sub> in the brain was assessed by
paraffin-embedded tissue blot (Figure 2, panels C and D) or
immunohistochemical analysis with 3F4 antibody (Figure 2,
panels E and F). Results for IC-inoculated animals showed
that PrP<sub>d</sub> strongly accumulated in a dense synaptic pattern
associated with nonamyloid plaques in the striatum, several
thalamic nuclei (Figure 2, panel E), the external cortex of
the colliculi, and the tegmental area. Other areas that were
slightly less affected (e.g., neocortex and hippocampus)
showed few coarse granules and synaptic deposits. The
cortical molecular layer and the corpus callosum were
devoid of PrP<sub>d</sub> (Figure 2, panel C). In orally inoculated
animals, PrP<sub>d</sub> was strongly accumulated in the striatum and
thalamus (Figure 2, panel D) but weakly accumulated in
the cortex. Immunohistochemical analysis showed synaptic
deposits (Figure 2, panel F), and some focal deposits were
evident in animals that survived longer. No plaques were
detected in orally inoculated animals.

**Conclusions**

We demonstrated that the agent of L-BSE can be
transmitted by the oral route from cattle to mouse lemurs.
As expected, orally inoculated animals survived longer
than IC-inoculated animals. Orally inoculated lemurs had
less severe clinical signs and symptoms, with no evidence
of motor dysfunction. It was previously suggested that
the agent of L-BSE might be involved in the foodborne
transmission of a prion disease in mink (11,12), a
species in which several outbreaks of transmissible mink
encephalopathy had been identified, notably in the United
States (13).

Our study clearly confirms, experimentally, the
potential risk for interspecies oral transmission of the agent
of L-BSE. In our model, this risk appears higher than that for
the agent of classical BSE, which could only be transmitted
to mouse lemurs after a first passage in macaques (14). We
report oral transmission of the L-BSE agent in young and
adult primates. Transmission by the IC route has also been

**Figure 1. Western blot analysis of protease-resistant prion protein in the brain (thalamus/hypothalamus) and spleen of mouse lemurs inoculated with a cattle-derived L-type bovine spongiform encephalopathy isolate by oral and intracerebral routes by using SHa31 monoclonal antibody against prion protein. Lanes 1, 7: cattle L-type BSE isolate (02–2528); lanes 2, 3: brain sample from intracerebral inoculation at 5 mg; lane 4: brain sample from oral inoculation at 50 mg; lanes 5, 6: brain sample from oral inoculation at 5 mg; lanes 8, 9: spleen samples from oral inoculation at 5 mg, positive and negative, respectively.**
reported in young macaques (6,7). A previous study of L-BSE in transgenic mice expressing human PrP suggested an absence of any transmission barrier between cattle and humans for this particular strain of the agent of BSE, in contrast to findings for the agent of classical BSE (9). Thus, it is imperative to maintain measures that prevent the entry of tissues from cattle possibly infected with the agent of L-BSE into the food chain.
