Brucellosis in Takins, China

To the Editor:

Brucellosis is a highly contagious bacterial disease and one of the world’s major zoonoses. It is responsible for enormous economic losses in livestock, and it threatens human health and wildlife populations (1). In most host species, brucellosis primarily affects the reproductive system, leading to concomitant loss in productivity of affected animals (1). Brucellae have been found in wildlife, such as bison, elk, and wild boar, potentially posing a threat for zoonosis (2). Currently, the genus Brucella comprises 10 species, which are divided according to host specificity and ability to cause chronic infections in human and animals (3, 4). Most Brucella species are associated primarily with certain hosts, presumably the result of evolutionary adaptation to a successful host. Brucella melitensis is the species most pathogenic in humans and the species most commonly involved in ovine and caprine brucellosis.

In January 2009, in the nature reserve in Qinling Mountains, China, hygromas were found on the knees, stifles, hocks, haunches, and bursae between the nuchal ligament and the primary thoracic spines of 10 free-ranging takins (Budorcas taxicolor). The hygroma contents and tissue samples were collected by using aseptic technique, packaged separately, cooled immediately, and stored frozen at -20°C until cultured. The samples were streaked onto blood agar and MacConkey agar and incubated aerobically or anaerobically with 5% CO2 at 37°C for 4 days. Tiny gram-negative cocccobacilli were isolated. The organism was nonmotile at 20°C and 37°C, and it stained red with the Stamp modification of the Ziehl-Neelsen method. The organism was identified as Brucella by the Vitek 2 GN identification system (bioMérieux, Marcy l’Étoile, France). The isolate was urease positive, catalase positive, and oxidase positive. It did not require carbon dioxide for growth and did not produce hydrogen sulfide. The isolate could be agglutinated by A- and M- monospecific antiserum but not by M-monospecific antiserum or rough Brucella-specific antiserum. It was sensitive to Berkeley and Iz phages at routine test dilution but not sensitive to Tbllisi, Weybridge, Firenze, and R/C phages. According to classical biotyping methods, the isolate was identified as B. melitensis biotype 2 (5).

Molecular identification by 16S rRNA gene sequencing was used in this study (6). According to nucleotide–nucleotide GenBank search by using BLAST (http://blast.ncbi.nlm.nih.gov/), the sequence was 100% identical to the sequences of 16S rDNA of brucellae, especially reference strains including B. melitensis 16M (GenBank accession no. NC_003317), B. abortus biovar 1 str. 9–941 (NC_006932), B. suis 1330 (NC_004310), B. canis American Type Culture Collection 23365 (NC_010103), and B. ovis American Type Culture Collection 25840 (NC_009505). The isolate was further confirmed as B. melitensis according to the 731-bp product by using AMOS-PCR, which discriminates among species by the unique locations of the IS711 element (7, 8). The restriction pattern of the omp2b gene by Hin1I was accordant with pattern 3 reported by Cloeckaert et al. (9); this finding further indicated that the isolate was B. melitensis (9).

The takin (Budorcas taxicolor) is a ruminant belonging to the family Bovidae, subfamily Caprinae, genus Budorcas (Figure). Takins are found in eastern Asia and Southeast Asia and are listed as “vulnerable A2cd” by the International Union for Conservation of Nature (10). Brucellosis might pose a major direct or indirect threat to the conservation of endangered species,
such as takins, and can be a source of conflicts among stakeholders in conservation efforts.

Several antelopes, such as takins, serows (*Capricornis sumatraensis*), and goral (*Naemorhedus goral*), occur sympatrically in the Qinling Mountains of China. Because brucellae are often transmitted by direct contact or exposure to a contaminated environment, it is possible that rather than being a natural reservoir for the bacteria, takins are infected horizontally by contact with birth exudates from other infected animals (2). However, information on brucellosis prevalence in those sympatric ruminants in China is insufficient. Therefore, further investigation and research are needed to test this hypothesis.

Whether takins are the reservoir host or an accidental host for *B. melitensis* is still unclear. To further understand the interaction of brucellae among wildlife, domestic animals, and humans, and for purposes of brucellosis management and control, systematic investigations of brucellosis prevalence among wildlife should be conducted.

This study was supported by grants to the Wildlife-borne Diseases Surveillance Project from the State Forestry Administration of China, the joint project of the National Wildlife Research Center of the US Department of Agriculture and the Institute of Zoology of the Chinese Academy of Sciences (O760621234), the Science and Technology Support Project of the Eleventh Five-Year Plan of China (2009BAI83B01), and the Special Major Project of the National Department of Science and Technology (2009ZX10004-109).

Measles and Secondary Hemophagocytic Lymphohistiocytosis

To the Editor: We found interesting the article by Lupo et al. about a case of fatal measles in an immunocompetent 29-year-old woman (Fatal measles without rash in immunocompetent adult, France; http://dx.doi.org/10.3201/eid1803.111300). Perhaps, however, the possible diagnosis of secondary hemophagocytic lymphohistiocytosis (HLH) should also have been considered in that setting.

HLH is a potentially fatal hyperinflammatory syndrome characterized by histiocytic proliferation and hemophagocytosis. HLH may be inherited (i.e., primary, familial, generally occurring in infants) or may occur at any age secondary to infection, malignancy, or rheumatologic disease. Secondary HLH is determined according to clinical criteria from the HLH Study Group of the Histiocyte Society, which require >5 of the following for a diagnosis: fever; splenomegaly; cytopenia (affecting >2 cell lineages); hypertriglyceridermia or hypofibrinogenemia; hemophagocytosis in the bone marrow, spleen, or lymph nodes; low or absent natural killer cell cytotoxicity; hyperferritinemia; and elevated levels of soluble CD25.

We conducted a PubMed search and found 5 articles that described 6 cases of HLH in patients with measles (1–5). Pneumonia was described in all of them (1–5), and central nervous system involvement was described in 3 (1,4). Four cases occurred in children, 3 of them immunocompetent (1,3–5). The 2 adults were an immunocompetent 18-year-old man who had acute respiratory distress (2) and a 19-year-old man with acute lymphocytic leukemia who had measles pneumonia and acute hemorrhagic leukoencephalitis (1). The only fatal case occurred in an immunocompromised 8-year-old boy with giant-cell pneumonia (3).

The identification of hemophagocytosis in bone marrow aspirate represents only 1 of the 5–8 criteria needed for a diagnosis of HLH; conversely, a bone marrow aspirate lacking hemophagocytosis does not rule out the diagnosis of HLH. Still, we believe HLH should be considered for any patient with fever and pancytopenia, especially in the presence of respiratory distress or multiorgan dysfunction. An appropriate therapy could save the patient (Secondary hemophagocytic syndrome in adults: a case series of 18 patients in a single institution and a review of literature; http://dx.doi.org/10.1002/hon.960).

In Response: We thank Iaria et al. (1) for their comments on our letter reporting an unusual case of fatal measles without rash in an immunocompetent woman who manifested cytopenias and an intractable acute respiratory distress syndrome (2). The authors suggest that secondary hemophagocytic lymphohistiocytosis (HLH) could have been considered in this patient.
