Cerebellar Cysticercosis Caused by Larval Taenia crassiceps Tapeworm in Immunocompetent Woman, Germany

Vasileios Ntoukas,1 Dennis Tappe,1 Daniel Pfütze, Michaela Simon, and Thomas Holzmann

Human cysticercosis caused by Taenia crassiceps tapeworm larvae involves the muscles and subcutis mostly in immunocompromised patients and the eye in immunocompetent persons. We report a successfully treated cerebellar infection in an immunocompetent woman. We developed serologic tests, and the parasite was identified by histologic examination and 12s rDNA PCR and sequencing.

Taenia crassiceps tapeworms are intestinal parasites of carnivores (final hosts), mostly foxes and dogs, in North America, Europe, and Russia. Rodents are natural intermediate hosts that harbor the cyst-like larvae (metacestodes, cysticerci) in their body cavities or subcutaneously, where the larvae proliferate by asexual budding (1). Prevalence among foxes in Germany and Lithuania is high (2), 24% and 26.4%, respectively. In contrast, prevalence in Denmark is low, only 0.2% (3). Although humans rarely serve as intermediate hosts, an increasing number of zoonotic infections have emerged in recent years (4–12). Infection of humans is thought to occur after consumption of food or water contaminated with infective ova shed in carnivore feces (1). All recognized cases involving the muscles or subcutis of humans have been associated with underlying immunosuppression (4,–7,12), except for 1 case (Ronald Neafie, pers. comm). In contrast, intraocular infections (8–10) do not seem to require an impaired immune system (Table).

We describe a case of intracranial T. crassiceps tapeworm cysticercosis with severe involvement of the cerebellum. Combined surgical removal of the larvae and treatment with albendazole and praziquantel led to a complete cure in this nonimmunocompromised patient. The organism was unequivocally identified by molecular methods, thus avoiding a misdiagnosis of Taenia solium tapeworm cysticercosis.

The Study

In 2011, in Regensburg, southern Germany, a 51-year-old German woman was hospitalized because of progressive headache, nausea, and vomiting. The signs and symptoms had started 2 weeks before, and intensity had been increasing ever since. At the time of admission, the patient showed cerebellar ataxia but no further neurologic deficits. She did not have fever or other symptoms. She had no known chronic preconditions or recent hospital stays and had never taken immunosuppressant drugs. She had no family history of neurologic symptoms or malignant diseases. Cranial computed tomography was performed and demonstrated a tumorous lesion of ≈30 × 30 mm in the right cerebellar hemisphere compressing the fourth ventricle. Magnetic resonance imaging revealed a multicystic mass with little perifocal edema (Figure 1). The patient’s leukocyte count was elevated (27.4 × 10⁹ cells), and a differential count indicated 84% neutrophils, 8% lymphocytes, and 4% eosinophils. Aspartate aminotransferase (129 U/L), alanine aminotransferase (335 U/L), and gamma glutamyl transferase (196 U/L) levels were elevated, and total plasma protein concentration was slightly lowered (4.7 g/dL). Kidney function test results, C-reactive protein levels, and gamma globulin levels were within normal limits.

Craniotomy revealed subdural and intracerebellar jelly-like tumorous tissue. The tumor, which consisted of multiple spherical masses with diameters of 2–4 mm, was resected. No infiltration of meningeal structures or the skull was evident.

Because an intracranial parasitosis or tumor was suspected, serum, tissue, and fluid from the cystic lesion were examined. Gross and histologic aspects of the excised tissue revealed typical structures for cestode larvae (Figure 2). Serum and tissue samples were sent to a reference laboratory for further examination. Serologic test results for echinococcosis, which used crude and recombinant antigen ELISAs, and indirect hemagglutination test results were negative (11). Commercial Western blots for cysticercosis and echinococcosis (LDBIO Diagnostics, Lyon, France) showed weak atypical bands of ≈47 kDa and 30 kDa, respectively (online Technical Appendix Figure 1, wwwnc.cdc.gov/EID/article/19/12/13-0284-Techapp1.pdf). For the tissue samples, cestode-specific PCRs selective for the parasite’s mitochondrial 12S rRNA gene

(13) and mitochondrial cytochrome c oxidase subunit I gene (14) were positive. After sequencing and conducting a BLAST search (www.ncbi.nlm.nih.gov/blast/Blast.cgi) of the 380-bp and 450-bp amplicons, we found that the sequences showed 99% and 100% homology with the *T. crassiceps* tapeworm, respectively.

A crude *T. crassiceps* ELISA similar to an in-house *Echinococcus multilocularis* assay was set up (11) by using laboratory-kept *T. crassiceps* tapeworm larvae from another human patient (1). Serum samples from 10 healthy blood donors served as negative controls, and a standardized threshold index of 1.0 was calculated. Because no serum from patients with proven *T. crassiceps* tapeworm infections was available to use as a positive control, we used serum from patients with histologically confirmed cystic echinococcosis (5 patients), alveolar echinococcosis (7 patients), and peripheral cysticercosis (2 patients). All serum samples were positive, showing indices of 1.2–9.1, 1.4–6.6, and 2.2–3.3, respectively. The patient’s serum, however, had an index below the threshold (0.76). When 5-µm cryosections from *T. crassiceps* tapeworm larvae were used for immunofluorescence tests, the patient’s serum exhibited a weak tegumental signal (online Technical Appendix Figure 2).

After surgery, the patient was given praziquantel (600 mg twice daily) and albendazole (400 mg twice daily) as described (1) for 3 months. The postoperative course was uneventful, the patient recovered rapidly, and there were no clinical or radiographic signs of recurrence after a follow-up period of 18 months. Extended imaging investigations showed no further sites of infection.

When the patient was asked about potential risk factors, she indicated that she had been living with her dog near a forest in a local rural area for many years. Consumption of wild berries or mushrooms possibly contaminated by fox feces could not be excluded. The dog, which had not regularly undergone deworming, had access to the garden and the nearby forest.

protoscolex showing numerous hooklets, similar to T. solium tapeworm

larvae. Original magnification ×40. Like the Taenia solium tapeworm

that causes cysticercosis, and in contrast to different tapeworms that

cause coenurosis (T. [Multiceps] multiceps, T. [Multiceps] serialis) or

echinoeoccosis, the T. crassiceps tapeworm has only 1 invaginated

protoscolex, but it is on a very long neck (Cysticercus longicollis). The

hooklets of T. crassiceps tapeworms are larger than those of T. solium

tapeworms and have a larger blade length than handle length. The

small hooklets measure 123 µm; the large hooklets measure 167 µm.

same variety of human tissues as T. solium, but do so much more rarely. Most infections, including the case reported here, have been reported from southern Germany (1,6) and France (5,7,12). Other infections of humans have been re-

ported from neighboring Switzerland and Austria and from

North America. Similar to the distribution of alveolar echi-

necoccosis in Europe (another larval cestode disease for

which the red fox is also the final host), a contiguous area

with microfoci of transmission could hypothetically be pos-

sible. Diagnosis depends on the radiographic image resem-

bling a racemose cysticercus (because of the multicystic

aspect of T. crassiceps tapeworm infections) and correct

identification of the parasite by gross morphologic and his-

tologic appearance by experienced pathologists or by mo-

lecular techniques. 12S rDNA PCR proved to be a useful

tool that is not widely used (13,14), and its use helped avoid

the misdiagnosis of T. solium tapeworm neurocysticercosis.

The diagnosis of T. crassiceps tapeworm infection is de-

manding for laboratories because no tests are commercially

available. As described here, unusual serologic reactions dis-

played on tests for other larval helminthoses should raise the

level of suspicion for a different causative agent. Of note,

the serologic diagnosis of neurocysticercosis caused by T. solium
can be difficult; commercial tests showed sensitiv-

ity <72% (15). Such a low sensitivity could hypothetically

explain the negative ELISA result for the patient reported

here, for whom no peripheral tissues were infected, in con-

trast to the control serum used. Thus, the true prevalence of

human disease caused by T. crassiceps tapeworms could be

underestimated, and future seroprevalence studies using

ELISA and immunofluorescence testing can possibly shed

more light on this type of infection. The source of infection

for this patient remains unclear, but her dog is probably the

major risk factor (1,8,10). As a preventive measure, carniv-

rous pets should undergo regular deworming.

Conclusions

In recent years, more reports of human infection with

T. crassiceps tapeworms have surfaced, possibly because

of increasing numbers of immunocompromised persons.

The patient described here showed no evidence of an im-

paired immune system, and the parasite was found in an im-

munologically privileged site. Similarly, for patients with

T. crassiceps larvae infection of the eye and for patients

with neurocysticercosis caused by T. solium, immunosup-

pression does not seem to be a prerequisite for infection. T. crassiceps tapeworm larvae are apparently able to infect the
