To the Editor: Pentastomiasis is a parasitic zoonotic disease with an incremental number of reported human infections caused by larval stages (nymphs) of pentastomes (1–3). The vermiform parasites are in their own phylum and are related to branchiuran crustaceans (2). Most human infections with these parasites are caused by Armillifer armillatus (2), a parasite endemic to western and central Africa. Most cases are reported from the Congo region and Nigeria, and occasionally infections in African immigrants to Europe and North America have been reported (4,5). Imported cases to Germany have not been reported. A. grandis, a related parasite from central Africa, has been rarely found (6), but A. moniliformis, a pentastome species from Asia, has recently reemerged and caused a human infection after ≈40 years in Malaysia (1).

Adult Armillifer spp. inhabit the respiratory tract of large snakes (Python spp.). These dioecious parasites produce large amounts of ova that are shed into the environment by snake feces and secretions. When intermediate hosts, such as rodents or other small mammals, ingest ova, larvae hatch, migrate to the viscera, encyst, and molt several times (3). Humans become accidental intermediate hosts after uptake of environmental parasite ova or by consumption of contaminated snake meat. We report an infection with A. armillatus in an African immigrant to Germany that was diagnosed by histopathologic analysis and confirmed by PCR.

In 2005, a 23-year-old man from Togo who had immigrated to Germany 3 years earlier showed development of acute myeloid leukemia. He subsequently underwent stem cell transplantation, which was followed by graft versus host disease. The patient died of sudden intracerebral hemorrhage and leukencephalopathy. His medical history also included α-thalassemia and a heterocytogous sickle cell trait, chronic hemolytic anemia, splenomegaly, and cardiomyopathy. He had been treated for schistosomiasis and filariasis.

An autopsy specimen showed several living pentastome nymphs of ≈2 cm in size, which were found in the subcapsular region of liver parenchyma. A presumptive diagnosis of visceral pentastomiasis caused by A. armillatus nymphs was made in accordance with the origin of the patient and the geographic distribution of the parasite.

Microscopic slides from patient specimens were retrieved from an archive and reanalyzed (Figure; online Technical Appendix Figure, wwwnc.cdc.gov/EID/article/19/3/12-1508-Techapp1.pdf). A pentastome-specific PCR targeting the 18S rDNA gene (2,7) was conducted after DNA extraction from formalin-fixed tissue on a remaining unstained microscope slide. The resulting 383-bp amplicon was sequenced, and BLAST analysis (www.ncbi.nlm.nih.gov/blast) confirmed 100% identity with A. armillatus (GenBank accession no. HM756289.1) and 99% homology with A. agkistrodontis (FJ607339.1) and A. moniliformis (HM048870.1).

Visceral pentastomiasis in humans is often asymptomatic and an incidental finding during surgery (1,3) or autopsy (8,9). In a large autopsy series from Malaysia, a pentastomiasis prevalence of 45.5% was found in adult Aborigines (8). In Nigeria, a rate of 33% was seen during autopsies of patients who had died of malignancies (9). However, a few severe and even lethal cases have been described for heavy A. armillatus and A. grandis infections in persons from Africa (4,6).

Diagnosis is achieved by gross pathologic and histopathologic analyses. Nymphs are found in the serosa around the liver and spleen, in liver parenchyma, mesenterium, intestine wall, and abdominal lymph nodes. The lungs or pleura are occasionally infected (3). Radiographic analysis may show typical C-shaped chest or abdominal calcificatons (10). Species identification is performed by counting annulations (A. armillatus 18–22,
A. grandis >25) and measuring the size of larval parasites (3). Recently, PCR has been used for diagnosis in veterinary infections (2,7).

For the patient in our study, molecular analysis identified human pentastomiasis by using a formalin-fixed microscope slide that had been stored for 7 years. A difference of 2 nt each was seen when the amplified nucleotide sequence was compared with database sequences of A. agkistrodonis and A. moniliformis. However, there is no database entry in GenBank for A. grandis, the geographically closest Armillifer species. Serologic assays have been developed for identification of A. armillatus (2), but no serum was available for retrospective analysis.

In special settings, such as tropical snake farming and pet keeping, pentastomiasis may be a public health concern (2). However, most infections have been linked to consumption of undercooked snake meat or other snake products (1).

Most immigrants who were given a diagnosis of visceral pentastomiasis were from Nigeria or the Congo region, and diagnoses were made after death. Molecular analysis is particularly valuable when only autopic paraffin-embedded patient material is available. For industrialized countries, where experience in morphologic identification of unusual parasite species is limited, molecular analysis is a valuable diagnostic tool. Our case-patient constitutes a record of imported Armillifer species pentastomiasis to Germany. Because of increasing international migration, more cases of pentastomiasis are likely to be seen.

Mycobacterium kyorinense Infection

To the Editor: Mycobacterium kyorinense is a nonpigmented, slowly growing mycobacterium that was initially isolated in 2007 from a patient with pneumonia in Japan (1,2). The sequences of the 16S rRNA, hsp65, and rpoB genes of M. kyorinense were closely related to, but different from, those of the type strains of M. celatum and M. branderi, the 2 most phylogenetically related species (1).

Biochemical tests, such as those for arylsulfatase activity, tellurite reduction, and heat-stable catalase, also distinguish M. kyorinense from M. celatum and M. branderi. In our initial report, in which this species was first recognized, we described 3 strains isolated from Japanese patients (1). Recently, 1 additional case was reported in Brazil (3). Here we describe 7 newly identified patients whose infection may have been caused by M. kyorinense.

In reviewing the characteristics of these 11 patients (10 from Japan and 1 from Brazil), we found no apparent contacts among them. Nine of the 11 patients had respiratory infections, 1 had lymphadenitis, and 1 had arthritis (Table). Of these, 9 patients fulfilled the criteria for infections of clinical significance (4) and were considered to harbor infection by M. kyorinense. Of the 9 patients with respiratory infections, 4 died as a result of the infection. These data suggest that M. kyorinense belongs to a class of nontuberculous mycobacteria that are pathogenic for humans and have substantial clinical effects.

Among the 10 patients for whom precise clinical records were available, 7 patients were treated with first-line tuberculosis drugs, mainly rifampin, isoniazid, and ethambutol, but these therapies were ineffective for all patients.
