High-Complexity *Plasmodium falciparum* Infections, North Central Nigeria, 2015–2018

Bitrus Yakubu, Ishaya Yohanna Longdet, Tony Horsefield, Dinchi Tyem Davou, Emmanuel Obishakin

The mass migration that occurred during 2009–2013 and after the insurgency in northeastern Nigeria could have increased malaria incidence and *Plasmodium falciparum* genetic diversity in North Central Nigeria. To determine *P. falciparum* sequence diversity in this region, we screened 282 samples collected in regional clinics during 2015–2018 for *Plasmodium* spp. and, with positive samples, determined *P. falciparum* infection complexity and allele diversity using PCR. Of 34 *P. falciparum*-positive samples, 39 *msp1*, 31 *msp2*, and 13 *glurp* alleles were detected, and 88% of infections were polyclonal. We identified trimorphic and dimorphic allele combinations in a high percentage of samples, indicative of a high infection complexity in the study population. High genetic diversity is a catalyst for the evolution of drug resistant-alleles. Improved measures (e.g., better drug quality, diagnostics) are needed to control *P. falciparum* transmission and reduce the potential for the emergence of drug resistance in Nigeria.

Malaria is endemic in Nigeria; its national prevalence among children 6–59 months of age is 27% (1). The World Health Organization World Malaria Report 2017 indicated that Nigeria accounted for 27% of the global malaria cases and 30% of the deaths in 2016 (2). The insurgency that occurred during 2009–2013 in northeastern Nigeria has been marked as one of the key factors responsible for driving this increased number of malaria cases and deaths; the insurgency disrupted the healthcare system, and up to 2.1 million persons were displaced (3–6). Added to the insurgency burden were communal conflicts between internally displaced persons (IDPs) and locals, which predominantly occurred in the states of Plateau, Benue, Taraba, Kaduna, and Nasarawa (3). Published reports established that 3 patterns of IDP movement transpired in Nigeria: migration to North Central Nigeria (defined as the states of Kwara, Niger, Nasarawa, Plateau, Benue, and Kaduna, and the Federal Capital Territory), economic migration from rural to urban areas, and secondary displacement of host communities because of communal conflicts (5).

The population displacement that occurred in North Central Nigeria was likely a key factor affecting the epidemiology of malaria transmission in this region. A high level of new clones of *Plasmodium falciparum* probably would have been introduced into the host communities of towns and cities experiencing influxes of IDPs. Immigration of infected persons into new areas can increase the rate of malaria transmission (7) and might subsequently result in infections of higher complexity and pathogens of more extensive genetic diversity in the host communities. In other malaria-endemic areas, population displacement, political unrest, and insurgency have been found to affect malaria epidemiology (8–10).

Meiotic recombination of *P. falciparum* parasites in *Anopheles* sp. mosquitoes has been proposed as the origin of the generation of novel alleles leading to new *P. falciparum* strains, and this cycle is likely to continue as long as there are vectors, parasites, and human hosts (11–13). Treatment failures occur more often in patients infected with higher numbers (≥3 vs. <3) of *P. falciparum* strains (14,15). Drug resistance and treatment failures are envisaged to be among the challenges to achieving elimination of malaria in Nigeria (16,17). Ajayi et al. (18) reported 3 cases of artemisinin-based combination treatment failure of *P. falciparum* infection that were later adequately cleared with quinine. However, health practitioners and professionals in Nigeria have determined that the failure to clear parasites and resolve clinical disease after drug treatment is the result of many factors (drug nonpotency, incorrect diagnosis, noncompliance with dosing regimen duration, use of substandard drugs, and drug interactions). These reports spurred us to investigate the complexity of *P. falciparum* infections and *P. falciparum* genetic diversity (allele frequencies) in the North Central region of Nigeria.

Merozoite surface protein 1 (*msp1*), merozoite surface protein 2 (*msp2*), and glutamate-rich protein (*glurp*) gene-based studies of *P. falciparum* genetic diversity and infection complexity have been extensively carried out in other parts...
of sub-Saharan Africa, but only a few studies have taken place in regions of Nigeria (19–24). Research is scant on the genetic diversity of *P. falciparum* in North Central Nigeria, and this knowledge is critical for the implementation of successful control measures (13). Earlier reports by Jelinek et al. (25) and Meyer et al. (12) showed that increased genetic diversity of circulating malaria parasites in a population increases the potential for the selection of drug resistance. In our study, we investigated *P. falciparum* genetic diversity and the complexity of *P. falciparum* infections by assessing *msp1*, *msp2*, and *glurp* allele frequencies and genetic diversity in densely populated areas of North Central Nigeria.

**Materials and Methods**

**Study Design**

During August 2015–April 2018, whole blood samples for this study were collected from patients treated at 6 randomly selected healthcare centers in 5 locations of North Central Nigeria: Jos (Plateau State), Karu (Nasarawa State), Kafanchan (Kaduna State), Lokoja (Kogi State), and Abuja (Federal Capital Territory) (Figure 1). We chose these locations because previously published reports indicated that IDP movement occurred in these areas during the peak periods of insurgency, communal conflicts, and economic migration. After collection, whole blood samples were stored at 4°C until we performed PCR analyses at the Department of Biochemistry in the Faculty of Medical Sciences, University of Jos (Jos, Nigeria). Our target was to analyze ≥50 representative archived whole blood samples from each of the 6 healthcare centers. We received permission to collect and analyze these samples from the National Code for Health Research Ethics Committee.

**PCR Screening for *P. falciparum***

We characterized *P. falciparum* isolates using the nested PCR methods of Snounou et al. (26) as modified by Singh.
et al. (27). These modifications included the use of a different genus-specific primer combination (rPLU-1 with rPLU-5 instead of rPLU-5 with rPLU-6) and the use of the nest-1 PCR product as the template for the genus-specific (nest-2) PCR. The primers for these PCRs (Table 1) were designed by using the *Plasmodium* small subunit rRNA genes (29) and synthesized by Inqaba Biotec (https://www.inqababiotech.co.za). We performed the nest-1 PCR, then the nest-2 PCR (to identify the samples positive for *Plasmodium* spp.), and then the *P. falciparum* species-specific PCR.

The nest-1 reaction mix contained 5 μL of DNA template, 25 μL of One Taq Quick-Load 2× Master Mix (New England BioLabs, https://www.neb.com), 1 μL of each primer (10 μmol/L rPLU1 and rPLU5), and 18 μL nuclease-free water. We used the following cycling program for the nest-1 PCR: initial denaturation at 94°C for 4 min; 35 cycles of 94°C for 30 s, 55°C for 60 s, and 72°C for 60 s; and a final extension at 72°C for 4 min. The nest-2 reaction mix was the same as the nest-1 reaction mix, except that we used 2 μL of the nest-1 PCR product as the template and different primers (rPLU3 and rPLU4). The *P. falciparum* species-specific reaction mix was the same as the nest-2 PCR reaction mix, except that we used different annealing temperatures (62°C for the nest-2 PCR and 58°C for the *P. falciparum* species-specific PCR).

Allele Diversity and Complexity of Infections

In genotyping PCRs, 32 persons were positive for *msp1*, 29
for *msp2*, and 31 for *glurp*. We found more genetic varia-
tion (i.e., more alleles) for the *msp1* gene than the *msp2*
or *glurp* genes. We detected a total of 39 *msp1* (16 *K1*, 13
MAD20, and 10 *RO33*), 31 *msp2* (16 *FC27* and 15 IC/3D7),
and 13 *glurp* clones in *P. falciparum*–positive blood sam-
ple (Tables 2, 3). A high percentage of the population had
evidence of polyclonal infections; ≥2 different-sized PCR
products (i.e., ≥2 alleles) were present on agarose gel for
the *msp1*, *msp2*, or *glurp* genes in 88% of the samples.
Similar studies conducted previously in Nigeria (mainly in
the southwestern part) during 2004–2014 showed less ge-
netic diversity (Table 3). In those studies, the total number
of clones detected were 4 for *K1*, 2 for MAD20, and 4 for
*RO33* of the *msp1* gene and 9 for *FC27* and 4 for IC/3D7
of the *msp2* gene. Polyclonal *P. falciparum* infections
were more prevalent in our study (multiplicity of infection
[MOI], i.e., parasite clones per sample, 2.4) than in the pre-
vious reports (MOIs 1.1 and 1.4; Table 3).

In our study, fragment sizes were 100–1,200 bp for
*msp1*, 150–1,200 bp for *msp2*, and 200–1,550 bp for *glurp*
(Figures 3–5). The highest number of clones seen for a
single allele in a single sample was 8 (with 8 clear bands
of the *FC27* allele); this sample came from a patient in Ka-
funchan. A number of samples contained only 1 clone: 8
samples contained a single clone of *K1*, 8 a single clone
of *RO33*, 6 a single clone of MAD20, 7 a single clone
of *FC27*, and 9 a single clone of IC/3D7.

The combinations of *msp1* family alleles observed
were *K1*, MAD20, and *RO33* (63%, 20/32); *K1* and MAD20
(3%, 1/32); *K1* and *RO33* (6%, 2/32); and MAD20 and
*RO33* (3%, 1/32). Infections were predominantly trimor-
phic (63%), and fewer were dimorphic (12%); 25% were
monomorphic. For the *msp2* allele family, dimorphic infec-
tions (*FC27 + IC/3D7*) occurred in 50% of the population;
35% of the population was positive for only IC/3D7 and
15% for only *FC27*. Many patients had infections with high
MOIs. The mean MOI per allele family was 2.4 for *msp1*
and 1.0 for *glurp* (Table 2). The wide occurrence of
trimorphic and dimorphic allele combinations is indica-
tive of high complexity of infection in the study popula-
tion.

We assessed the frequency of the occurrence of each
allele in the population. We categorized clones into mo-
lecular weight groups differing by 50 bp for clear discrimi-
nation from other clones and elimination of errors that
would result from estimating the molecular weight on agra-
rose gels. For the *msp1* allele family, the *K1* allele of size
200–250 bp was detected at the highest frequency (n = 18),
followed by the MAD20 allele of fragment size 150–200 bp
(n = 11) and the *RO33* alleles of fragment sizes 100–150

In this prospective cross-sectional study, we investigated the transmission being prevalent year-round.

eas of Nigeria; this factor has led to the mosquitoes that po increased transmission during this period can be explained by the open gutter and sewage systems present in urban ar.

of polyclonal infections and the frequency of clones were clonal. Paired t tests showed that the temporal distribution of polyclonal infections and the frequency of clones were statistically significant (p<0.05). During the dry season, the person infected with the highest number of clones (8 clones) was sampled, as well as others infected with 4–5 clones. The finding that polyclonal infections were more common in the dry season was unexpected. However, the increased transmission during this period can be explained by the open gutter and sewage systems present in urban areas of Nigeria; this factor has led to the mosquitoes that potentiate malaria transmission being prevalent year-round.

We did not attempt to compare the distribution patterns of the allele families by location because the number of P. falciparum–positive samples in some locations was low. However, an analysis of the seasonal patterns of diversity showed that 60% of the infections that occurred during the dry season (November–March) and 50% of those that occurred during the wet season (April–October) were polyclonal. Paired t tests showed that the temporal distribution of polyclonal infections and the frequency of clones were statistically significant (p<0.05). During the dry season, the person infected with the highest number of clones (8 clones) was sampled, as well as others infected with 4–5 clones. The finding that polyclonal infections were more common in the dry season was unexpected. However, the increased transmission during this period can be explained by the open gutter and sewage systems present in urban areas of Nigeria; this factor has led to the mosquitoes that potentiate malaria transmission being prevalent year-round.

### Discussion

In this prospective cross-sectional study, we investigated P. falciparum genetic diversity and the complexity of P. falciparum infection in North Central Nigeria because a high level of genetic diversity and infection complexity was a likely aftermath of the influx of IDPs into the region. We hypothesized that a high level of genetic diversity would be found in the region partly as a result of immigration of P. falciparum–infected IDPs into the region. High genetic diversity of malaria parasites circulating in a population could serve as a risk factor for genetic recombination and the generation of novel alleles (11–13). We found that 63% of the Plasmodium spp.–positive samples were positive for P. falciparum. Our PCR screening results cannot be used as an estimate of the prevalence of P. falciparum in North Central Nigeria, but this finding has revealed that non–P. falciparum malaria species are circulating in this region and infecting humans. The finding of 37% positivity for non–P. falciparum Plasmodium spp. is high compared with previous reports of low-level prevalence (0.4%–6.3%) in other parts of Nigeria (30–33). An epidemiologic study of non–P. falciparum malaria species circulating in the North Central region would be vital for national malaria control. Treatment failures reported by some authors (16,17) in Nigeria could be related to incorrect diagnosis and hence inappropriate drug administration. Artemisinin–based combination therapy is recommended for the treatment of P. falciparum malaria, but chloroquine plus primaquine is the first-line regimen for P. vivax malaria (34).

We detected the msp1, msp2, and glurp alleles in most patients positive for P. falciparum parasites, and these alleles had high genetic variability. Many samples from infected patients contained multiple alleles, and the genetic variation was more extensive with the msp1 and msp2 allele families than with the glurp allele. Overall, 88% of the

†Defined as number of parasite clones per sample.
population had evidence of polyclonal infection with ≥1 of the allelic forms. We discovered 10–16 *msp1* clones and 15–16 *msp2* clones. This finding does not corroborate results of similar previous studies from southwestern Nigeria, in which 1–4 *msp1* clones and 3–9 *msp2* clones were found (Table 3). We detected a total of 39 *msp1*, 31 *msp2*, and 13 *glurp* alleles, which is quite high compared with the reported values in other regions of Nigeria (30,32) and other countries of West Africa (21). Infections with pathogens harboring high numbers of alleles could influence the emergence of resistance (33), considering that, in this scenario, multiple alleles are exposed to the same chemotherapeutic agents. The high level of trimorphic, dimorphic, and monomorphic infections in the population is evidence of extensive genetic diversity. Our work revealed a higher frequency of occurrence of polyclonal infections and infections with *P. falciparum* parasites of multiple genotypes, as well as infections of higher MOIs, compared with previous studies (30,33,36).

The question yet to be answered, however, is whether polyclonal infection is a frequent occurrence in Nigeria. The frequent occurrence of this phenomenon in a single geographic area has been determined to be an early indicator for the emergence of alleles associated with drug resistance (11,35). The high number of polyclonal infections seen in North Central Nigeria could be attributed to a high level of genetic recombination and high evolutionary pressure on the *msp1*, *msp2*, and *glurp* genes in this region, which could partially be attributed to the high level

![Figure 3](image-url). Allele frequency of *msp1* in persons with *Plasmodium falciparum* infection, North Central Nigeria, 2015–2018. The K1 allele of size 200–250 bp was detected at the highest frequency (n = 18). The next highest detected were the MAD20 allele of fragment size 150–200 bp (n = 11) and the RO33 alleles of fragment sizes 100–150 bp (n = 9) and 650–700 bp (n = 9).

![Figure 4](image-url). Allele frequency of *msp2* in persons with *Plasmodium falciparum* infection, North Central Nigeria, 2015–2018. The most frequently detected alleles were the FC27 allele of size 250–300 bp (n = 9) and the IC/3D7 allele of size 400–450 bp (n = 9).
of movement into the North Central region (the economic hub of the nation) for commercial reasons. Drug resistance of \textit{P. falciparum} parasites is a highly complex mechanism involving multiple genes, \textit{pfk13} being a gene responsible (37). Work by Oboh et al. (36) and Ebenebe et al. (37) indicated that in 2018 drug resistance of malaria pathogens to artemisinin-based combination therapy was not an immediate public health threat for southwestern Nigeria. Nonetheless, a nationwide study should be performed to comprehensively evaluate for the presence of \textit{P. falciparum} drug resistance genes with techniques such as next-generation sequencing and genome walking (38,39). Oboh et al. (36) were able to detect synonymous mutations (not validated AA mutations of the \textit{pfk13} gene), such as the nucleotide change from CCG to CCA in the \textit{pfk13} gene in \textit{P. falciparum} from southwestern Nigeria, and called for close monitoring of parasites in Nigeria. A nationwide study should also be conducted to comprehensively determine the genetic diversity of \textit{P. falciparum} and complexity of infections in Nigeria. Determining the genetic diversity of malaria parasites in the North Central region, as well as for the entire nation of Nigeria in general, is needed for the design of a national treatment policy, vaccine development, and immunogenicity studies.

The frequency of polyclonal infections in southwestern Nigeria during 2004–2014 can be described as low and not extensive compared with the level discovered in this study. The period of this study (2015–2018) falls within peak periods of communal conflicts in Nigeria (2009–2017), which resulted in the displacement of persons in the North Central region (40,41). Our findings suggest a relationship between the high number of polyclonal infections discovered in North Central Nigeria and the movements of IDPs into the region, although a previous study of the \textit{msp2} genotype by Oyedeji et al. (42) in Lafia (Nasarawa State) showed a high level of genetic diversity in 2005–2006. A high level of introduction of new \textit{P. falciparum} clones could have occurred in the host communities in the towns and cities that experienced IDP influxes.

A major limitation of this study is the lack of a comparison of the genetic diversity of \textit{Plasmodium} spp. in patients in other regions of the country. However, previous studies conducted in southwestern Nigeria provided a baseline for comparison to determine whether the level of \textit{Plasmodium} spp. genetic diversity discovered in this study was different and thus potentially associated with the movement of IDPs. The correlation would have been more comprehensive if we had also included comparison groups from other regions and specific IDP camps in our investigation.

In summary, this study revealed a high level of \textit{P. falciparum} genetic diversity and infection complexity in North Central Nigeria and suggested that this complexity might be a result of the insurgency and movement of IDPs that occurred in Nigeria during 2009–2017. A deliberate effort is needed to control malaria and eliminate the risk for the evolution of resistance alleles across Nigeria, but particularly in this region of Nigeria, which is the economic hub of the nation and at highest risk for distributing new strains worldwide. The information we generated on \textit{Plasmodium} spp. epidemiology and genetic diversity could serve as a source in a database to be used for policy development on nationwide malaria control and intervention programs for Nigeria. Our work also led to the establishment of a laboratory capable of performing PCR methods to evaluate malaria epidemiology in the region, which could be used for future comprehensive malaria control measures.
Acknowledgments

We sincerely thank Bitrus Matawal for his valuable assistance in securing the national code for ethics approval to conduct this healthcare research. We also appreciate the medical laboratory scientists in the selected healthcare centers who provided aliquots of archived blood samples analyzed in this study.

This study was sponsored by the Biotechnology Development Center of the University of Jos.
