We report a case of *Plasmodium knowlesi* malaria imported to central Europe from Southeast Asia. Laboratory suspicion of *P. knowlesi* infection was based on the presence of atypical developmental forms of the parasite in Giemsa-stained microscopic smears. We confirmed and documented the clinical diagnosis by molecular biology techniques.

The simian malaria parasite, *Plasmodium knowlesi*, is an emergent public health threat for persons traveling to Southeast Asia (1). We report a case of *P. knowlesi* malaria imported to central Europe from Southeast Asia.

On June 25, 2018, a 27-year-old woman returned to Poland after an 8-month tourist stay in Southeast Asia (Appendix Figure 1, http://wwwnc.cdc.gov/EID/article/25/9/19-0445-App1.pdf). The patient did not use malarial chemoprophylaxis during her travels. While in Sumatra, Indonesia, she experienced 2 episodes of subfebrile body temperature of <38°C. After returning to Poland, she reported having general malaise, weakness, chills, and a low-grade fever. She consulted a family physician, who observed multiple young trophozoites in the erythrocytes, with a delicate, thin ring of cytoplasm. Some also had narrow band shapes. In addition, we saw mature schizonts with <16 merozoites, large round gametocytes, and notable amounts of hemozoin pigment (Appendix Figure 2). ELISA revealed a high level of *Plasmodium* sp. IgM/ IgG (52 U/mL), but we could not identify the *Plasmodium* species from these features. We later used PCR to confirm *P. knowlesi* infection from peripheral blood collected in EDTA tubes and frozen at −20°C. In brief, we extracted DNA from a 1.2-mL venous blood sample by using an automated nucleic acid extractor, MagCore HF16 Plus, with a MagCore genomic DNA large volume whole blood kit (RBC Bioscience Corp., https://www.rbcbioscience.com), according to standard protocol. To identify the *Plasmodium* species, we used nested PCR according to Komaki-Yasuda et al. (2). In patients with previously described *P. falciparum* malaria, we have observed a specific band for the parasite. We did not observe this band in the case-patient’s sample, suggesting infection with another *Plasmodium* species. The *P. vivax* primers did not yield amplification, but the *P. knowlesi* oligos resulted in clear bands, indicating that this patient was infected with *P. knowlesi* (Figure). In addition, the *P. knowlesi* band diminished after malarial therapy, demonstrating treatment efficacy.

On the basis of the patient’s travel history, clinical signs and symptoms, test results, and World Health Organization guidelines (3), we diagnosed uncomplicated *P. knowlesi* infection. The patient received oral artemether and lumefantrine combined with intravenous doxycycline and the parasites cleared in microscopic smears within 4 days. The patient’s fever subsided, her blood morphology
and biochemistry parameters improved, and her levels of inflammatory and coagulation system markers decreased. In addition, PCR was negative for *P. knowlesi* DNA in peripheral blood after treatment. During a 3-month follow-up period, morphological and biochemical laboratory parameters all normalized, and the level of *Plasmodium*-specific antibodies diminished to ≤28 U/mL.

In conclusion, we describe a rare case of *P. knowlesi* infection imported to Poland in a traveler returning from Southeast Asia. Previous research studies report imported cases of *P. knowlesi* malaria in travelers returning to other countries in western and northern Europe, including Spain, Italy, France, Germany, and Sweden (4–10). Travelers from Poland increasingly choose Southeast Asia as a common and popular destination. With that in mind, parasitology laboratories in Poland could diagnose *P. knowlesi* more often as an etiologic agent of tropical malaria. The ambiguous morphology and low number of parasites seen in microscopy make diagnosing *P. knowlesi* difficult. Proper diagnosis relies on thorough epidemiology, including travel history, augmented with molecular biology techniques.
