Severe acute respiratory syndrome coronavirus 2 did not replicate efficiently in 13 bat cell lines, whereas severe acute respiratory syndrome coronavirus replicated efficiently in kidney cells of its ancestral host, the *Rhinolophus sinicus* bat, suggesting different evolutionary origins. Structural modeling showed that RBD/RsACE2 binding may contribute to the differential cellular tropism.

Coronavirus disease (COVID-19) is a global pandemic, affecting 213 countries with >2.7 million confirmed cases and 190,000 fatalities as of April 25, 2020 (1). Its causative agent was identified as severe acute respiratory syndrome coronavirus (SARS-CoV) 2 (SARS-CoV-2), which belongs to the same coronavirus species as SARS-CoV and SARS-related CoVs (SARSr-CoVs) in horseshoe bats (genus *Rhinolophus*) (2,3). Given the history among some early case-patients of visiting the Huanan seafood market in Wuhan, China, and its genetic close relatedness to SARSr-CoVs in bats and pangolins (2,4), SARS-CoV-2 was suspected to have emerged from wild animals, particularly bats, similar to SARS-CoV. SARS-CoV was a recombinant virus that originated from Chinese horseshoe bats (*Rhinolophus sinicus*) before it infected palm civets and then humans (5).

Studying cellular tropism may provide clues to the host range and possible origin of zoonotic viruses. For example, SARS-CoV could replicate efficiently in kidney cells of its primary origin, *R. sinicus*, but not in other tested bat cells (6). To elucidate the possible origin of SARS-CoV-2, we tested susceptibilities of bat cell lines developed from different species commonly found in southern China to infection by SARS-CoV-2 in comparison with SARS-CoV. The selected bat species harbored a diverse set of coronaviruses, including SARSr-CoVs and Middle East respiratory syndrome–related coronaviruses (MERSr-CoVs), which pose potential health threats to humans (7). We also performed structural modeling of the virus/host receptor-binding interface.

The Study
SARS-CoV strain HKU-39849 was isolated in Hong Kong during the SARS epidemic as previously described (8). SARS-CoV-2 strain HK20 was isolated from a patient with COVID-19 in Hong Kong in early February 2020 (3). Thirteen primary or immortalized bat cell lines from 6 different bat species were subjected to infection with SARS-CoV and SARS-CoV-2 at multiplicity of infection of 0.1 as described previously (6,9,10), except with the addition of 2 µg/mL trypsin. The bat species included *Miniopterus pusillus*, *Pipistrellus abramus* (harboring *Pipistrellus*-BatCoV-HKU5), *R. sinicus* (harboring SARSr-BatCoVs, *Rhinolophus*-BatCoV-HKU2, *Rhinolophus sinicus*-BatCoV-HKU32), *Tylonycteris pachypus* (harboring *Tylonycteris*-BatCoV-HKU4), *Rousettus leschenaultii* (harboring many viruses, including Rousettus-Bat-CoV-HKU9 and Rousettus-Bat-CoV-HKU10), and *Myotis ricketti* (harboring *Myotis*-BatCoV-HKU6). Vero cells from African green monkey kidney were used as positive control (Figure 1; Appendix, https://wwwnc.cdc.gov/EID/article/26/12/20-2308-App1.pdf). We determined viral replication efficiency by quantitative reverse transcription PCR (qRT-PCR) on cell culture supernatants (Table 1) (6). Cells were considered susceptible to viral infection if qRT-PCR on day 5 postinfection showed ≥1 log₁₀ increase in viral titer with statistical significance (p<0.05 by Student t-test).

SARS-CoV but not SARS-CoV-2 can replicate efficiently in R. sinicus kidney cells; SARS-CoV showed 3.48 log_{10}-fold increase in viral titer. In contrast, only SARS-CoV-2 can replicate in R. sinicus lung cells, but at a low viral titer (1.08 log_{10}-fold increase). Moreover, SARS-CoV-2 can replicate more efficiently (1.46 log_{10}-fold increase) in R. sinicus brain cells than SARS-CoV (1.09 log_{10}-fold increase), albeit still at low viral titer (Table 2; Figure 1). Both SARS-CoV and SARS-CoV-2 can also replicate in P. abramus kidney cells with low viral titers: 1.45 log_{10}-fold increase for SARS-CoV and 1.71 log_{10}-fold increase for SARS-CoV-2. We observed cytopathic effects in SARS-CoV-infected R. sinicus kidney cells and SARS-CoV- or SARS-CoV-2-infected P. abramus kidney cells with rounding of cells (Appendix Figure 1). We performed immunofluorescence assay on those cell lines with >1 log_{10}-fold increase in viral load (Appendix Figure 2). M. pusillus kidney cells; R. leschenaultii kidney, brain, intestine, and lung cells; T. pachypus kidney cells; and M. ricketti kidney and lung cells did not support SARS-CoV or SARS-CoV-2 infection. Furthermore, both SARS-CoV and SARS-CoV-2 replicated less efficiently in Vero cells at 33°C than at 37°C, whereas no difference in viral replication in R. sinicus kidney cells was observed between 33°C and 37°C (Appendix Figure 3).

To elucidate whether the receptor-binding interface is a contributing factor for cellular tropism, we modeled the structure of the SARS-CoV-2 receptor binding domain (RBD) with that of human
angiotensin-converting enzyme 2 (hACE2), R. sinicus angiotensin-converting enzyme 2 (Rs-ACE2), and P. abramus angiotensin-converting enzyme 2 (Pa-ACE2) using homology modeling by SWISS-MODEL (https://swissmodel.expasy.org) as described previously (11), based on the crystal structure of SARS-CoV-RBD/hACE2. The sequence identity between SARS-CoV RBD (template) and SARS-CoV-2 RBD (template) was >50% and the interface for all RBD/hACE2/Rs-ACE2. The interface for RBD/Pa-ACE2 was similar to that of RBD/hACE2 (Figure 2), implying that Pa-ACE2 may also serve as the host receptor for SARS-CoV-2.

Conclusions
The ability of SARS-CoV but not SARS-CoV-2 to replicate in R. sinicus kidney cells, consistent with previous findings (12), may suggest a different evolutionary origin and path of SARS-CoV-2. SARS-CoV was most closely related to SARSr-Rs-BatCoVs from Yunnan, China, suggesting R. sinicus as its primary origin. It could also use Rs-ACE2 as receptor for cell entry (13), which may explain the efficient replication of SARS-CoV in R. sinicus kidney cells. Although SARS-CoV-2 is closely related to SARS-CoVs in bats and pangolins, none of the existing animal viruses represents the immediate ancestor of SARS-CoV-2. SARS-CoV-2 was most closely related to SARSr-RatCoV-RaTG13 (96.1% genome identity) in Rhinolophus affinis from Pu’er, Yunnan (2), except that its RBD region was closest to pangolin-SARSr-CoV-MP789 (86.9% nucleotide identity) in smuggled pangolins from Guangdong, suggesting that SARS-CoV-2 may have evolved through recombination (3). The inability of SARS-CoV-2 to efficiently infect and replicate in R. sinicus cells may imply that R. sinicus bats were unlikely to be its proximal origin. However, bats are the primary origin of SARS-CoV, human coronavirus 229E (HCoV-229E), and probably MERS-CoV; therefore, SARS-CoV-2 most likely originated from bats. One possibility is that SARS-CoV-2 has restricted bat species tropism. Other bat species, such as R. affinis, may harbor the ancestor of SARS-CoV-2 and can be tested for cellular susceptibilities in future studies. It is also possible that SARS-CoV-2 can no longer

*CoV, coronavirus; CPE, cytopathic effects; SARS, severe acute respiratory syndrome.
replicate in bat cells because of substantial genetic adaptation, such as through natural evolution in an intermediate host before infecting humans.

The difference in critical residues for receptor binding between SARS-CoV and SARS-CoV-2 may have contributed to their differential infectivities in R. sinicus cells, as suggested by results from structural modeling of the receptor-binding interface. Whereas SARS-CoV RBD was most closely related to SARSr-Rs-BatCoV-WIV1 from R. sinicus, SARS-CoV-2 RBD was most closely related to the RBD region of pangolin-SARSr-CoV-MP789 from pangolins (14). Mutagenesis studies are needed to investigate whether changes of these amino acid sites may affect binding affinity to the ACE2 of different hosts and restore the infectivity of SARS-CoV-2 in R. sinicus cells.

The restricted cellular tropism of SARS-CoV and SARS-CoV-2 is different from that of MERS-CoV, which showed broad species tropism in bat cells. MERS-CoV could replicate in ≥5 bat cell lines (M. ricketti lung, P. abramus kidney, R. sinicus kidney and lung, and R. leschenaultii kidney cells) from 3 bat families (6). Although dromedary camels were the immediate source of MERS-CoV, bats were suggested to be the ultimate evolutionary origin (10,15). Of note, SARS-CoV, SARS-CoV-2, and MERS-CoV could all replicate in P. abramus kidneys at low titers. Structural modeling supported that P. abramus ACE2 could serve as host receptor for SARS-CoV and SARS-CoV-2. P. abramus is known to harbor Pi-BatCoV-HKU5 from the subgenus Merbecovirus (containing MERS-CoV) but not members of Sarbecovirus (containing SARS-CoV and SARS-CoV-2) (10,15). P. abramus is a potential accidental host for spillover of and source for emergence of diverse coronaviruses including SARSr-CoVs.

Acknowledgments
We thank Agriculture, Fisheries and Conservation Department, Government of Hong Kong, for capture of bats for bat cell development and expert opinion.

Differential Tropism of SARS-CoV and SARS-CoV-2 in Bat Cells

Appendix

We tested 13 cell lines from *Rousettus leschenaultii* bat (intestine, kidney, brain, lung), *Rhinolophus sinicus* bat (lung, brain, kidney), *Miniopterus pusillus* bat (kidney), *Pipistrellus abramus* bat (kidney, lung), *Tylonycteris pachypus* bat (kidney), and *Myotis ricketti* bat (kidney, lung). Cells were subject to infection by SARS-CoV and SARS-CoV-2 viruses (isolated from Vero cells, Passage 6) with MOI of 0.1 and with 2 post-adsorption washings. We performed the testing in triplicate. Supernatants and cell lysates were harvested at day 0 and day 5 postinfection. Viral titers and β-Actin mRNA were determined by real-time quantitative RT-PCR. Viral load was expressed as normalized fold change in log$_{10}$. *Rhinolophus sinicus* brain and kidney cells and *Pipistrellus abramus* kidney cells can support SARS-CoV infection, demonstrated by ≥1 log$_{10}$ increase in viral load at day 5 (p<0.05). *Rhinolophus sinicus* lung and brain cells and *Pipistrellus abramus* kidney cells support SARS-CoV-2 infection.
Appendix Figure 1. Cytopathic effects (CPE) in infected *Rhinolophus sinicus* kidney, *Pipistrellus abramus* kidney and Vero cells on day 5 postinfection. CPE was compared between *Rhinolophus sinicus* kidney cells that were uninfected (control) (A), and infected with SARS-CoV (B) and SARS-CoV-2 (C). CPE was compared between *P. abramus* kidney cells that were uninfected (control) (D), infected with SARS-CoV (E) and SARS-CoV-2 (F). CPE was compared between Vero cells that were uninfected (control) (G), infected with SARS-CoV (H) and SARS-CoV-2 (I).
Appendix Figure 2. Antigen expression of SARS-CoV and SARS-CoV-2 in Vero and bat cell lines. Selected cell lines were subject to infection by SARS-CoV (A) and SARS-CoV-2 (B). Antigen expression of SARS-CoV and SARS-CoV-2 with MOI of 0.1 were assessed with immunofluorescence staining. Infected cells were fixed with 4% paraformaldehyde at 24 hpi and immunolabelled with rabbit anti-SARS-CoV-NP and SARS-CoV-2-NP primary antibody, followed by fluorescein isothiocyanate (FITC) conjugated goat-antirabbit antibody and mounting solution with DAPI stain. Bars represent 50 μm.
Appendix Figure 3. Susceptibilities of Vero and *Rhinolophus sinicus* kidney cell lines to infection by SARS-CoV and SARS-CoV-2 at different temperatures. *Rhinolophus sinicus* kidney (Rs-Kidney) and Vero cells were subject to infection by SARS-CoV (A) and SARS-CoV-2 (B) with MOI of 0.1 at 33°C and 37°C. Supernatants and cell lysates were harvested at day 0 and day 5 postinfection. Viral titers and β-Actin mRNA were determined by real-time quantitative RT-PCR. Viral load was expressed as normalized fold change in log₁₀. Standard deviations of triplicate samples were shown. Asterisk * indicates p<0.05.
