During widespread community transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), transmission chains are sometimes unclear. Although often unavailable, viral genome sequencing can complement epidemiologic investigations.

In fall 2020, the Connecticut Department of Public Health analyzed data from contact tracing interviews and initially identified 5 cases of coronavirus disease (COVID-19), the illness caused by SARS-CoV-2, in employees of a single workplace within 1 week. One employee also worked at an elementary school and fitness center; in those settings, several contacts of this employee later tested positive for SARS-CoV-2. At the time, the weekly community case rate in this county was 141 cases/100,000 persons (https://portal.ct.gov/Coronavirus/COVID-19-Data-Tracker), reflecting high community transmission according to thresholds set by the Centers for Disease Control and Prevention (CDC) (1). To better characterize this cluster, we investigated its scope, phylogenetic relationships, and factors associated with transmission.

We defined a cluster-associated case as COVID-19 in a coworker, primary contact, or secondary contact of the initial 5 employees; all cases were diagnosed by a viral test (i.e., antigen or nucleic acid amplification tests) authorized for emergency use by the Food and Drug Administration (2). We defined the investigation period as starting 1 week before symptom onset of the earliest workplace case and ending 2 weeks after symptom onset of the last workplace case. We assessed symptoms, onset dates, adherence to prevention strategies, and potential exposures. This activity was reviewed by CDC and was conducted in accordance with applicable federal law and CDC policy (e.g. 45 C.F.R. part 46.102(l) [2], 21 C.F.R. part 56; 42 U.S.C. 241(d); 5 U.S.C. 552a; 44 U.S.C. 3501 et seq.).

Overall, we identified 16 cluster-associated cases in 6 workplace employees, 3 school staff members and students, 2 fitness center attendees, and 5 household contacts. Symptom onset was generally earlier among workplace employees than among school and fitness center contacts (Figure 1).

The workplace employed 35 persons and provided in-person customer service. After the first

1Preliminary results from this study were presented at the 2021 Council of State and Territorial Epidemiologists Annual Conference; June 13–17, 2021; https://www.csteconference.org.
employee (W-1) experienced symptoms on day 1 and tested positive for SARS-CoV-2, the workplace closed and recommended SARS-CoV-2 screening for other employees. In addition to the 5 initial cases, we identified 1 other case in a workplace employee (Figure 1). All 6 employees worked during the week before their symptoms began (Appendix 1 Figure 1).

In total, 4 of the 6 employees agreed to be interviewed (Appendix 1 Table 1). W-1 reported a potential exposure outside the workplace during the week before symptom onset. Two employees (W-2 and W-5) had contact with each other outside of work. No other employees reported contact with coworkers or members of coworkers’ households outside the workplace. Some employees were unable to maintain 6 feet of distance from coworkers and occasionally removed masks near coworkers. To increase air circulation, ventilation system fans were run continuously. Customers were not required to wear masks, and customer visits lasted 45–60 minutes.

One employee (W-3) also worked at an elementary school that offered in-person education 5 days a week. W-3 worked at the school on outbreak days 1–3; W-3’s symptoms developed on day 3. Three school contacts of W-3 subsequently tested positive for SARS-CoV-2 infection: a staff member (S-1) and 2 students (S-2 and S-3). S-1, a staff member, spent most of their time in a neighboring classroom but had brief contact with W-3 while substituting for W-3’s classroom. W-3 and S-1 reported strict adherence to prevention measures, including masking and social distancing, and did not have contact outside of school. To improve ventilation, the classroom windows were kept open. Among ≥15 students in W-3’s classroom, 2 asymptomatic students (S-2 and S-3) tested positive for SARS-CoV-2. S-2 was tested after a family member (S-2 [HH1]) had COVID-19 symptoms; another family member (S-2 [HH2]) later experienced symptoms as well. S-3 was tested after being notified that another person in the classroom tested positive for SARS-CoV-2.

W-3 taught an indoor fitness class on day 2, the day before their symptom onset. Approximately 6 clients attended the 1-hour class. Attendee F-1 experienced symptoms on day 5; attendee F-2 experienced symptoms on day 7. A household contact of F-2 (F-2 [HH]) later tested positive for SARS-CoV-2. W-3 and F-1 reported that attendees wore masks before and after the class but removed them during distanced (i.e., >6 feet) exercise. Information regarding facility ventilation was unavailable.

We acquired 13 specimens for viral genome sequencing. Specimens were unavailable for 2 workplace employees (W-2 and W-5) and 1 student household contact (S-2 [HH2]). The resulting genomes clustered into 2 separate lineages (Appendix 1 Figure 2). Cluster 1 comprised 11 genomes, of which 9 were identical or differed by 1 mutation. These 9 genomes were extracted from samples from W-3, W-3’s household contact, the school staff and students, the fitness center attendees, and household contacts of persons at the school and fitness center (Figure 2). The other 2 genomes in cluster 1 were isolated from W-1 and W-6. W-1 was the only employee to work during the infectious period (defined as beginning 2 days before symptom onset); however, sequences for W-3 and W-6 differed from W-1’s sequence by ≥3 mutations. Cluster 2 comprised genomes isolated from a workplace employee and the household contact of another employee (Figure 2); there was no known epidemiologic link between these 2 persons.

Conclusions
We found that the 16 members of a single COVID-19 cluster were involved in multiple transmission chains.
Transmission Chains within COVID-19 Cluster

Epidemiologic and genomic evidence supported transmission in the school and fitness center but not the workplace. These findings highlight challenges in accurate delineation of SARS-CoV-2 transmission chains and emphasize the benefits of combined epidemiologic and genomic investigation.

Although diagnostic specimens are often discarded by laboratories soon after testing, rapid identification of this cluster enabled the acquisition of specimens from 13 of the 16 cases. Our results suggest that infection was directly transmitted from W-3 to ≥6 other persons within their household, school, and fitness center. Classroom transmission of SARS-CoV-2 is uncommon in the context of prevention strategies such as masking and distancing; previous studies have suggested that most school-associated cases are acquired outside of school (5,6). However, our results suggest that staff-to-staff and staff-to-student transmission occurred in this classroom. This investigation also adds to evidence that indoor exercise without masks can facilitate SARS-CoV-2 transmission (7,8). Fitness centers might consider moving high-exertion exercise outdoors, improving ventilation, and promoting mask use during indoor exercise. Mask use during indoor exercise was mandated in Connecticut later in November 2020 (9).

Genomic data did not indicate SARS-CoV-2 transmission among workplace employees. Divergence among viral sequences of workplace employees and the SARS-CoV-2 evolutionary rate of ≈1 mutation per 2 weeks (10) suggest that the 4 other workplace cases were each acquired independently. However, workplace transmission from unidentified employees or customers remains possible. In addition, a workplace employee and household contact had unrelated sequences, suggesting that they also were infected independently (Figure 2). This apparent workplace cluster, disproven by sequencing, highlights challenges in defining transmission chains during widespread SARS-CoV-2 community transmission. These findings highlight the crucial role of genomic sequencing in clarifying transmission chains.

Rabies vaccines are highly effective, but delivering them can be challenging. The challenge is even greater for stray animals, which might not trust a stranger trying to deliver a life-saving vaccination.

How can public health officials ensure that stray dogs (and the people around them) are protected against rabies? Some researchers may have an answer:

Oral vaccines in dog treats.

In this EID podcast, Dr. Ryan Wallace, a CDC veterinary epidemiologist, explains an innovative strategy for delivering safe and effective oral vaccines.

Multiple Transmission Chains within COVID-19 Cluster, Connecticut, USA, 2020

Appendix 1

Appendix Methods

Genomic Sequencing

Nucleic acid was extracted from available original severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) diagnostic specimens (300 μL) using the MagMAX viral/pathogen nucleic acid isolation kit (Thermo Fisher Scientific, https://www.thermofisher.com). Sequencing libraries were prepared using the Ligation Sequencing Kit and the Oxford Nanopore Technologies Native Barcoding Expansion pack (https://nanoporetech.com) as described in the ARTIC Network protocol with V3 primers (1) with the following modifications: cDNA was generated with SuperScriptIV VILO Master Mix (Thermo Fisher Scientific), all amplicons were generated using 35 cycles of amplification, amplicons were normalized to 15 ng for each sample, end repair incubation time was increased to 25 minutes followed by an additional bead-based clean-up, and all clean-up steps used a ratio of 1:1 bead-to-sample ratio. Twenty-five ng of the final library was loaded on a MinION R9.4.1 flow cell. The ARTIC Network RAMPART application was used to monitor approximate genome coverage for each sample during sequencing (https://github.com/artic-network/rampart). Fast5 files were basecalled using the Guppy basecaller 4.4.0 fast model. Consensus genomes were generated using the ARTIC bioinformatic pipeline (https://artic.network/ncov-2019/ncov2019-bioinformatics-sop.html), which uses Nanopolish to call variants (2). A threshold of 20× coverage was required for each amplicon to be included in the consensus genome.

Multiple extraction controls were included for each RNA extraction batch and tested negative for SARS-CoV-2 RNA by reverse transcription PCR. No-template controls were introduced for each run at the cDNA synthesis and amplicon synthesis steps and were taken through the entire library preparation and sequencing protocol to detect any cross-contamination.
For each control in each run, <1,000 total reads were observed. A subset of reads in control samples aligned to the SARS-CoV-2 genome, but no position of the genome had >20 reads (enough data to influence the generation of a consensus genome).

**Phylogenetic analysis**

Consensus genomes were aligned using MAFFT within an augur pipeline (3,4). Sites near the 5’ and 3’ end of the genomes were masked alongside other problematic sites (5). The phylogenetic analysis dataset consisted of genomes from this study along with 570 globally representative genomes from GISAID (https://www.gisaid.org; Appendix Table 2). The tree was rooted using 2 genomes from early periods of the pandemic: Wuhan/Hu-1/2019 (GISAID accession no. EPI_ISL_402125) and Wuhan/WH01/2019 (GISAID accession no. EPI_ISL_406798).
