several genetic and antigenic differences and suggested poor reactivity to the contemporary human seasonal influenza vaccine.

This reported case is considered independent of the previously reported variant infection in Denmark (4), because the 2 viruses are genetically distinct (Table). The symptoms were also different; the earlier case was in an elderly patient with comorbidities who experienced classical influenza-like illness, but in this case, a previously healthy adult of younger age experienced unusual severe and sudden illness. Influenza-associated convulsions in adults are rare (6) and mostly accompanied by fever or encephalitis, which was not observed in this patient.

The identification of variant IAVs emphasizes the zoonotic potential of these strains and highlights the importance of continued monitoring of both human and swine IAVs. The reported case suggests a need for focusing on early registration of swine exposure for humans with influenza-like illness, as well as increased measures to reduce the swine IAV exposure risk for people with occupational contact with swine.

Acknowledgments

We thank the laboratory technicians from the National Influenza Center at Statens Serum Institute for technical assistance in the laboratory. We also thank the patient for collaboration through the interviews and for allowing publication of the case.

This work has been conducted as part of the national influenza surveillance in Denmark, which is funded by the government, and as part of the FluZooMark project, funded by the Novo Nordisk Foundation (grant no. NNF19OC0056326).

About the Author

Ms. Andersen is a PhD student at the Department of Health Technology, Technical University of Denmark and at the National Influenza Center, Statens Serum Institut, Denmark. Her research interests are the genetic evolution of influenza A viruses at the human/swine interface and using bioinformatics to identify genetic markers of zoonotic transmission.

In Valencia, Spain, permanent rodent control campaigns are the responsibility of The Pest Control Section of the Health Service of Valencia City Council. As part of its tasks, the Section traps *Rattus norvegicus* and *R. rattus* rats in standard snap traps in the sewage system of Valencia. The trapped rodents were preserved in their entirety at −20°C and subsequently, to determine the potential reservoir role of zoonotic parasitic diseases, we defrosted the rats and analyzed the endoparasites.

In 2021, we collected 29 adult *A. cantonensis* nematodes (21 female and 8 male) from the organs of the first 27 trapped rats (25 *R. norvegicus* and 2 *R. rattus*) under a stereomicroscope once the rats had been dissected. The nematodes were detected in the pulmonary arteries of 2 *R. norvegicus* rats and 1 *R. rattus* rat; 7 young nematode adults were also found in the brain of the same *R. rattus* rat. Adult females showed the typical barber pole spiral of lungworms of the genus *Angiostrongylus* (Figure, panel A). After clarifying adult male worms with Amman’s lactophenol and studying their morphology (Figure, panels B–D), we found that the measurements were consistent with rat lungworm species of *A. cantonensis* (Table) (1,2).

The parasite morphology, its microhabitat, and the nature of the definitive hosts clearly suggested that the parasites were *A. cantonensis*. To confirm species identification, we isolated total genomic DNA by using the DNeasy Blood and Tissue kit (QIAGEN, https://www.qiagen.com) according to the manufacturer’s instructions. We confirmed nematode species identity by PCR and sequencing of the cytochrome c oxidase subunit 1 (3); all sequences obtained were clustered with *A. cantonensis*. The phylogenetic tree grouped the *A. cantonensis* lungworms from Valencia close to the published sequences MK570629 and MN227185, corresponding to *A. cantonensis* lungworms isolated from Tenerife and Mallorca, respectively (Appendix Figure 1, https://wwwnc.cdc.gov/EID/article/28/12/22-0418-App1.pdf). We submitted the sequences we obtained to GenBank (accession no. ON819883 for the female specimen and ON819884 for the male). Likewise, when we sequenced the second internal transcribed spacer region, we found that our specimens formed a clade that differed from the other species of *Angiostrongylus* (Appendix Figure 2). We also submitted those sequences to GenBank (accession no. OM829831 for the male specimen and OM829832 for the female).

Male and female adult *A. cantonensis* lungworms live in the pulmonary arteries of *Rattus* rats, their preferred definitive hosts (4). Intermediate hosts are terrestrial or freshwater mollusks, such as snails and slugs. The female worms lay eggs, which give rise to L1 larvae that penetrate the alveolae and are swallowed by the rat and shed in the feces. After ingestion by an intermediate host, L1 larvae molt into L3 larvae. When infected mollusks are ingested by a rat, the subsequent phase takes place in the rat brain, where L3 larvae turn into young...
Lungworms have been reported and lungworms, a dangerous invasive species, agents of a potentially fatal emerging infectious disease, are spreading into locations beyond their typical tropical/subtropical distribution, probably favored not only by globalization but also by climate change. Epidemiologic surveys of rat populations in Europe, preferably in urban/peri-urban areas, with the involvement of government entities, pest control agencies, and experts in parasitic zoonoses, should help minimize future potential human infections.

## Acknowledgment

We thank the Health Service of Valencia City Council for overseeing and promoting this research in the city.

Laboratory Features of Trichinellosis and Eosinophilia Threshold for Testing, Nunavik, Quebec, Canada, 2009–2019

Prolonged eosinophilia is characteristic of trichinellosis. To determine the optimal eosinophil threshold for reflex Trichinella testing, we examined all 43 cases in Nunavik, Quebec, Canada, during 2009–2019. Using receiver operating characteristic analysis, we determined that eosinophil counts \( \geq 0.8 \times 10^9 \) cells/L should prompt consideration of trichinellosis and testing to rapidly identify potential outbreaks.

Trichinella nativa infection is associated with ingestion of parasitized sylvatic animals and periodic outbreaks among residents of northern Canada (1–3). In the Arctic region of Nunavik in Quebec, outbreaks associated with polar bear and walrus consumption have prompted public health interventions, including a highly successful community-led active surveillance system that examines hunted meat for evidence of Trichinella encystment (4,5). We report a 10-year case series of Trichinella infection in Nunavik and describe the laboratory features. Eosinophilia is a well-characterized feature of infection that is readily available for most cases. We performed receiver operating characteristic (ROC) analysis to define an optimal threshold of eosinophilia to prompt reflex Trichinella antibody testing and rapid reporting to public health authorities for timely outbreak investigation (1–3).

In a retrospective test-negative case-control study, we reviewed laboratory and public health records to identify cases of trichinellosis in Nunavik that occurred from 2009 through 2019. Our study was approved by the Research Institute of the McGill University Health Centre Research and Ethics Board (REB #2020-5312).

We first reviewed all requests for Trichinella serologic testing sent from Quebec to the National Reference Centre for Parasitology, the only testing site in Quebec, during 2009–2019 (Appendix, https://wwwnc.cdc.gov/EID/article/28/12/22-1144-App1.pdf). To define an initial set of cases (with positive Trichinella serologic results), we selected specimens originating from Nunavik. One author (L.B.H.) reviewed the charts and confirmed cases if the clinical evolution was compatible with the positive serologic results. Because trichinellosis is notifiable by provincial law, we cross-referenced cases with the public health database to identify other cases determined epidemiologically and reviewed those charts. We defined a set of region-matched controls as those with negative Trichinella serologic results. Those controls are therefore persons from the general population, from the same region who had clinical manifestations that prompted testing for trichinellosis. Although serologic results early in the disease course could be negative, chart review of controls did not yield additional suspected cases on the basis of clinical evolution. We extracted available clinical and laboratory data by chart review at the McGill University Health Centre and at regional health centers in Nunavik. We calculated summary statistics and tests (t-test and \( \chi^2 \)), comparing cases and controls by using R (6), and generated ROC curves by using the pROC R package (7).

We identified 43 cases of trichinellosis and a set of 31 region-matched controls (Table). We excluded 4 possible case-patients with weakly positive serologic results but ambiguous clinical manifestations consistent with past infection. Information on signs and
