To explore the competence of American robins as a reservoir for Lyme disease spirochetes, we determined the susceptibility of these birds to tickborne spirochetes and their subsequent infectivity for larval vector ticks. Robins acquired infection and became infectious to almost all xenodiagnostic ticks soon after exposure to infected nymphal ticks. Although infectivity waned after 2 months, the robins remained susceptible to reinfection, became infectious again, and permitted repeated feeding by vector ticks. In addition, spirochetes passaged through birds retained infectivity for mammalian hosts. American robins become as infectious for vector ticks as do reservoir mice, but infectivity in robins wanes more rapidly.

Lyme disease spirochetes (Borrelia burgdorferi s.l.) perpetuate in cycles involving rodent reservoir hosts, such as white-footed mice (Peromyscus leucopus) in eastern North America (1) and Apodemus spp. mice in Eurasia (2). Such hosts readily become infectious to vector ticks and appear to remain so lifelong. They serve as natural reservoirs of infection because numerous subadult vector ticks parasitize them, they are abundant, and they remain in constant residence in tick-infested sites. Rats (Rattus norvegicus and R. rattus) (3,4) and European dormice (Glis glis and Eliomys quercinus) (5,6) are similarly competent and locally important hosts to these pathogens. Although hares (Lepidus timidus) support infection with Lyme disease spirochetes in Europe (7), the competence of rabbits for these spirochetes has not been proven. A related spirochete, B. andersonii, appears to be specific to American rabbits (8,9). Ungulates, however, are not competent as hosts for Lyme disease spirochetes. Deer in intensely enzootic sites fail to infect vector ticks (10,11), and cattle and sheep exposed to infected vector ticks never become infectious (12). Lyme disease spirochetes infect diverse mammals, but not all of them serve as competent hosts.

Certain birds may also contribute to the transmission of Lyme disease spirochetes. Numerous vector ticks parasitize birds in nature, including spirochete-infected larval ticks that presumably acquired infection from these birds (13-19). Seabirds appear to maintain such a cycle on Arctic islands (20). In an enzootic site, American robins (Turdus migratorius) are considered to be an avian candidate as a reservoir of infection because they are locally abundant, forage in ground and brush vegetation, and are frequently infested by vector ticks (21). Catbirds (Dumetella carolinensis) in enzootic sites, however, appear not to infect vector ticks (22). Although spirochetes have been isolated from naturally infected European blackbirds (Turdus merula) (15), a laboratory study failed to demonstrate reservoir competence of these birds (23); the reason for this discrepancy remains unclear. Nymphal vector ticks occasionally become infected after feeding on spirochete-exposed pheasants (Phasianus colchicus); these birds, however, cannot contribute to transmission because larval ticks seem not to feed on them, either in the laboratory or in nature (24,25).
Emerging Infectious Diseases Vol. 6, No. 2, March–April 2000

Research

Chickens (Gallus gallus) become infectious, but only transiently and only when they are about a week old (26). Spirochetes inoculated by syringe can be detected in various tissues of canaries (Serinus canaria), bobwhite quail (Colinus virginianus), and Japanese quail (Coturnix coturnix) (27-29). The competence of candidate reservoir birds as hosts for tickborne spirochetes has not been thoroughly evaluated.

Tickborne Lyme disease spirochetes may readily infect certain birds, and these birds may subsequently infect numerous vector ticks. Therefore, we determined the susceptibility of American robins to tickborne spirochetes and their subsequent infectivity for larval deer ticks (Ixodes dammini, which differ from I. scapularis [30]). American robins are suitable candidate hosts because they are infested naturally by numerous vector ticks. We evaluated the reservoir competence of captive robins and determined whether they could subsequently be reinfested and reinfected by vector ticks and whether spirochetes passed through birds remain infective to rodents.

Materials and Methods

American robins were captured in mist nets in Brookline, MA (U.S. Fish and Wildlife Scientific Collecting Permit# MB719506-0), and maintained at 20°C with a photoperiod of 16:8 hrs (L:D) (Animal Welfare Assurance# A-3431-01). To establish that these birds had not already been infected by Lyme disease spirochetes, nymphs derived from xenodiagnostic larval deer ticks that had engorged on them were examined by dark-field microscopy. No spirochete-infected ticks were found. The birds were held in captivity for 6 months before they were exposed to infected ticks.

The colony of laboratory-raised deer ticks was originally isolated from ticks captured in Ipswich, MA, and was maintained by feeding adults on rabbits and subadults on outbred laboratory mice. To infect ticks, larvae were fed on outbred laboratory mice infected with the N40 strain of B. burgdorferi s.s. The resulting infected nymphal ticks were used to infect the robins. Xenodiagnosis was used to determine whether host animals had become infected by spirochetes; larval ticks were permitted to feed on them and the resulting nymphs were examined for spirochetes by dark-field microscopy. The larval ticks used for the xenodiagnosis were in their third generation of continuous laboratory breeding and had not previously been exposed to spirochete-infected hosts. Engorged ticks were held at 20±2°C over supersaturated MgSO4 in sealed desiccator jars with 16 hours of light per day. Hatched or molted ticks remained in screened vials until they were placed on hosts 2-4 months later.

To infest the robins with subadult ticks, each bird was restrained while ticks were brushed onto its head and neck. Each bird was then placed in a cotton bag suspended over water and kept in the dark for approximately 3 hours to limit their activity. The birds were then caged individually over pans of water in cages with wire-mesh floors and fronts (Safeguard Products, New Holland, PA). The contents of the pans were inspected twice a day, and detached ticks were removed promptly. The birds were exposed three times to nymphal ticks to test their susceptibility to repeated feeding (Figure 1). The first and last of these infestations also served to infect them. Xenodiagnostic larval ticks were permitted to feed on these robins nine times during the study.

Figure 1. American robins with attached nymphal deer ticks (Ixodes dammini).

Results

To evaluate the reservoir competence of birds for Lyme disease spirochetes, we exposed each of four American robins to the bites of 12 spirochete-infected nymphal deer ticks and determined the duration of their subsequent infectivity for larval deer ticks. The presence of spirochetes in these infecting nymphs was verified by dark-field microscopic examination of the gut contents of the resulting adults; virtually all (97%) contained spirochetes. Birds were exposed initially to
xenodiagnostic larvae at the same time they were exposed to the infecting nymphs. Xenodiagnosis was repeated after two days and at intervals for six months. Although larval ticks feeding simultaneously with the infected nymphs failed to acquire spirochetes, two birds infected xenodiagnostic larvae within 6 days after exposure to infected nymphs (Figure 2). All four birds were infectious to xenodiagnostic ticks that detached 12 days after exposure and infected 88% (+6.6) of ticks for at least another 3 weeks (Figure). Infectivity waned by 2 months and disappeared by 6 months. Almost all the ticks became infected that fed 2 and 4 weeks after the birds were infected (Table 1). American robins are fully but transiently competent as hosts for Lyme disease spirochetes.

We then determined whether American robins tolerate reinfection by tickborne spirochetes. Six months after they were initially infected, when vector ticks no longer acquired spirochetes from them, eight infected nymphs were permitted to engorge on each bird. All four robins regained infectivity for ticks within the next 2 weeks (Figure 2). Virtually all xenodiagnostic larval ticks that fed on three of these reinfected birds acquired spirochetes, and a third of them did so on the fourth bird. Although spirochete-infected robins only transiently infect vector ticks, the birds remain tolerant to reinfection and become infectious again.

*Each interval indicates the days on which xenodiagnostic ticks detached from their hosts.

The ability of nymphal deer ticks to reinfect American robins was evaluated by recording their feeding success. On initial exposure, 96% of 48 nymphs feeding on the four birds engorged successfully; 98% of 40 nymphs engorged 3 weeks later; and 82% of 32 nymphs engorged 6 months later, when the birds were exposed for the third time. The robins appear to freely tolerate repeated feeding by nymphal deer ticks.

To determine whether spirochetes passed through birds retain infectivity for mice, we permitted nymphs that had acquired infection as larvae from birds to feed on mice. The ticks that were used had acquired spirochetes 3 weeks after their avian hosts had been infected. Each of four outbred laboratory mice was exposed to six of the resulting nymphs. Two weeks later, 10 xenodiagnostic larval ticks were permitted to engorge on each of these mice. All but one of the 40 resulting nymphal ticks acquired spirochetes (Table 2). Spirochetes, therefore, remain infectious to mammals after a tickborne passage through birds.

Discussion

A competent reservoir host for the agent of Lyme disease readily acquires infection from vector ticks, permits spirochetes to proliferate, and readily infects vector ticks. In white-footed mice, infection generally becomes established after a single feeding by an infectious tick, and more than half retain infection for approximately 6 months (31). As many as three-quarters of the...

*Xenodiagnostic ticks that had engorged on each bird were used to infect the corresponding mouse.*

larval ticks that feed on such mice acquire infection, which subsequently wanes. Hamsters are similarly infectious (32). The various murids, glirids, voles, and scirrids that have been tested appear as reservoir-competent for spirochetes as are cricetids (2,5,6,33). Although certain genospecies of the Lyme disease spirochetes are said to be more mouse-adapted than others (34), no experimental evidence is available to support this concept. Rodents, in general, are readily infected by Lyme disease spirochetes, and most remain infectious to vector ticks for at least 6 months.

The standard of proof that has been applied to rodent reservoirs of spirochetal infection has not previously been applied to candidate avian reservoirs. Certain birds, including quail and canaries, can readily be infected by syringe-inoculated spirochetes. Spirochetal DNA generally becomes detectable in the viscera (27-29), and viable spirochetes can be cultured from these tissues. Tickborne spirochetes infect pheasants (24) and week-old chickens (26). About a third of these chicks infect ticks, but they remain infectious for only a week. Adult pheasants infect about a quarter of vector ticks that engorge on them. European blackbirds appear not to be susceptible to tickborne infection (23). American robins, however, appear far more reservoir-competent. Robins bitten by spirochete-infected nymphal ticks subsequently infect larval ticks, and virtually all larvae become infected after feeding on these birds throughout the following month. Infectivity declines, however, and few ticks acquire infection from these birds after approximately 3 months. Certain, but not all, bird species can readily be infected by Lyme disease spirochetes and subsequently become highly but transiently infectious.

A competent reservoir host tolerates feeding by both subadult stages of vector ticks. Although nymphs feed readily on pheasants, larvae seldom attach to these birds, either in nature or in the laboratory (24). About as many nymphal as larval deer ticks attach naturally to American robins (21). Several times as many larvae as nymphs, however, feed on white-footed mice in nature (35). Nymphal vector ticks attach more readily to rats, dormice, or the American reservoir host (*P. leucopus*) than to European mice (*Apodemus* spp.) or voles (2,3,5,31). Perhaps particular subadult stages of vector ticks are more readily attracted to certain vertebrate animals than to others.

To be competent as reservoir hosts for Lyme disease spirochetes, an animal must tolerate repeated feedings by vector ticks. White-footed or laboratory mice serve as hosts to deer ticks almost as readily during their fifth exposure as their first (36). Voles are much less tolerant (37), and rabbits (unpub. obs.) and guinea pigs (38) seldom tolerate more than one episode of attachment. Vector ticks feed repeatedly on American robins as successfully as on the natural rodent reservoirs of the Lyme disease spirochete.

Spirochete-infected larval ticks frequently are taken from birds in Lyme disease-enzootic areas. Of 20 species of North American passerine birds that were parasitized by larval vector ticks, 45% hosted spirochete-infected larvae (13,18). Spirochetes infected 10% to 40% of these batches of infected ticks. In Europe, 81% of 16 bird species harbored infected ticks; of these cohorts, 11% to 75% of the larval ticks were infected (17). Because Lyme disease spirochetes infect <1% of questing larval vector ticks captured in nature and because inherited infection is exceedingly rare (39,40), these larval ticks most likely acquired spirochetes from their avian hosts. Nevertheless, the avian host-range of Lyme disease spirochetes remains to be defined.

An effective reservoir of infection for a pathogen would generate for each primary
infection at least as many secondary infections. The contribution of various alternative reservoir hosts for Lyme disease spirochetes, however, can be compared by estimating the proportion of infections in nymphal vector ticks that derive from a particular vertebrate population. This calculation includes estimates of feeding density of vector ticks on the candidate reservoir host, its local density, and its prevalence of infection (2,5). At least twice as many vector ticks appear to acquire infection from a population of edible dormice (Glis glis) as from other rodents locally abundant in Central Europe (5). Similar evidence implicates white-footed mice in eastern North America (1). Information that would permit comparable estimates of the reservoir significance of local populations of birds, however, remains unavailable. Thus, it is still uncertain whether a bird, although reservoir-competent for the spirochete, may serve as an important reservoir in nature.

Because the prevalence of Lyme disease spirochetes in American robins has not yet been determined for a representative enzootic site, the importance of these birds as reservoir hosts remains speculative. Robins may contribute to the force of transmission of the agent of Lyme disease, because these locally abundant birds are reservoir-competent and may be infested by numerous larval ticks. Of the larvae that feed on peridomestic birds in North American enzootic sites, approximately three-quarters appear to engorge on robins (21). Although they may be about as abundant as white-footed mice, robins appear to forage more frequently on lawns than do mice (21). The contribution of robins to the peridomestic risk for Lyme disease may depend on the ability of engorged larval ticks detaching from the birds to develop in such habitat. Questing nymphal ticks appear less prevalent on lawns than on other vegetation in residential enzootic sites (41). Birds are more vagile than mice, which might dilute risk by diffusing infected ticks into sites in which transmission is unlikely. Alternatively, their vagility might seed new foci of transmission, if ticks detach in sites that are suitable for their development. Certain migratory passerines have been associated with long-distance dispersal of vector ticks (17-19). Robins may contribute to the emergence of Lyme disease in previously unaffected sites to the extent that the season of their migration overlaps with that of the activity of subadult vector ticks.

Our finding that American robins are reservoir-competent for Lyme disease spirochetes warrants further epizootiologic studies, including estimates of the prevalence of spirochetes in these birds in nature.
